

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

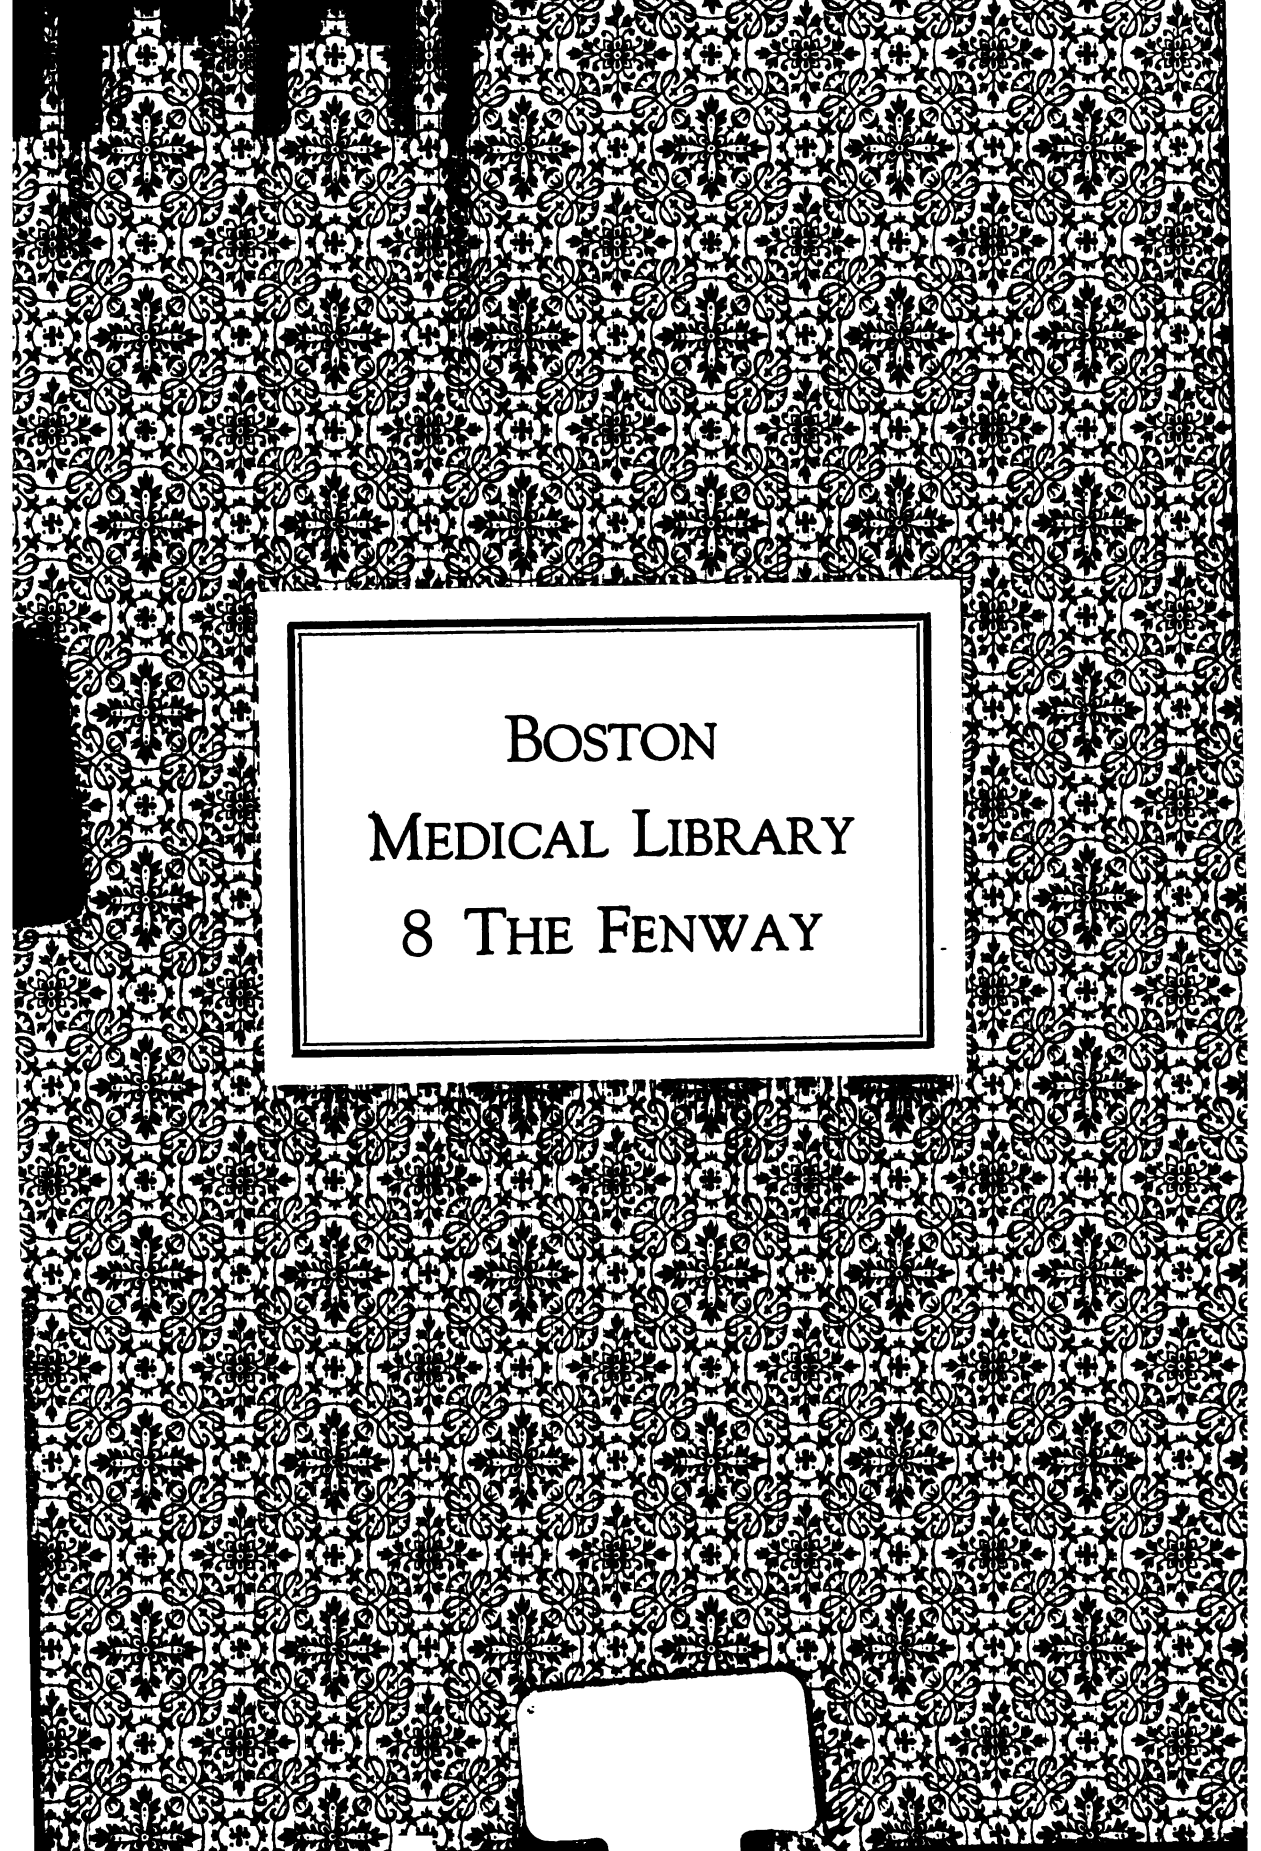

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

### THE ANTITOXIN TREATMENT OF DIPHTHERIA.\*

B. H. DETWILER, M.D.,  
Williamsport, Pa.

The simultaneous discovery of the bacillus of diphtheria by the German investigators Klebs and Loeffler demonstrated such progress in pathological research that these gentlemen have been honored by the world naming that organism the Klebs-Loeffler bacillus. The antitoxin of diphtheria is the natural

sequence, the appearance of which has been awaited by an expectant world. The helplessness of the profession in this terrible disease, that has so devastated nations, is best expressed in the multitude of specifics employed, and in the therapeutic negation known as the expectant treatment. The advent of the hypodermic injection of the antitoxin of diphtheria was coldly received by the profession, who, smarting from the disappointment in the effect of tuberculin upon the bacillus of tuberculosis when they expected so much from Koch's discovery, tested it slowly; and with this hesitancy followed the loss of thousands of lives; but when by its own merit it demonstrated its value, it was gladly hailed

\* Read before the Lycoming Medical Society, December 4, 1896.

by a suffering world. The former empirical plan of calling all membranous exudates of the tonsils and fauces, diphtheria, led to unreliable data; but now, when exudates are tested by the microscope, and a reliable antitoxin serum is used at a sufficiently early period of diphtheritic invasion, the result is uniformly a speedy recovery, with few sequelæ. The tendency to recovery is shown in from twelve to twenty-four hours by reduction of temperature, gradual proliferation of exudates, and a return of the desire for food. The more protracted the invasion, the less reliable is the antitoxin treatment and the greater the percentage of mortality. Professor Paltauf, of Austria, publishes in the *Lancet* statistics of 1103 cases of diphtheria in which antitoxin was employed, with the result of 970 recoveries and 133 deaths, equivalent to a mortality of 12.5 per cent. He lays much stress upon the early use of the serum, for in the cases where the injections were made on the second day of the disease the mortality amounted to but 6.7 per cent., whereas in the cases where the antitoxin treatment was begun on the third day the mortality amounted to 19 per cent.; if on the fourth day, to 23 per cent.; if on the fifth day, to 31 per cent.; and if on and after the sixth day, to 33.3 per cent. Professor Paltauf makes mention of the epidemic of diphtheria in Ischl, where in December, 1895, all the children died who had not received the antitoxin treatment, whereas in January, 1896, in the case of sixteen children attacked with the disease and treated with antitoxin, the result was in every way successful.

The first case of diphtheria in this city to be treated by antitoxin (March 10, 1895) was under the care of Dr. Charles Youngman, and proved fatal: the injections were not made sufficiently early in the course of the disease. Dr. Mohn, of Jersey Shore Junction, treated about that time four cases, with recovery. The City Hospital has purchased at wholesale diphtheria antitoxin for the use of the profession, enabling them to secure it promptly and at wholesale rates, and thus saving many lives. The first case of diphtheria cured by antitoxin in this city was in the contagious ward of the hospital in 1895, depending exclusively upon the antitoxin treatment. The result was so satisfactory that the serum was accepted as the coming remedy. In subsequent cases mixed treatment was used with it, with such uniform success that any one now losing a diphtheria patient without using antitoxin serum is held culpable.

Dr. G. Franklin Bell states that he had eighteen cases, seven males and eleven females, aged from one and a half years to fourteen years, all but one in good condition; period of invasion from two to five days; diagnosis not confirmed by cultures. Five of these had two injections of antitoxin, thirteen had one each. The membrane was upon the tonsils in thirteen, upon tonsils and nose in five, upon tonsils and pharynx in eight, and in the larynx in none. Three had nephritis. There was no paralysis. All recovered. In six cases antitoxin was exclusively relied upon, and in twelve a mixed treatment of bichloride and calomel internally was used, with local spray 1:2000 bichloride every two hours; Behring's preparation was used in sixteen cases, and Mulford's in two.

Dr. Geo. D. Nutt says: "I have seen six cases of croup. All seemed to be membranous. I gave antitoxin to all; intubated three of them. All got well but one, a small child, who died of pneumonia." He has just used serum on a case of diphtheria forty-eight hours old; membrane on pharynx and tonsils; temperature 103°. Twelve hours after injection the temperature was 99.5°, membrane off one tonsil and throat; in three days all the membrane was gone.

Dr. Gilmore, of Westport, writes November 10: "I injected antitoxin into a child of seven with laryngeal diphtheria following invasion of tonsils and pharynx. The stenosis was not great, but marked. She has greatly improved; temperature and pulse have become normal, but aphonia is still present. Should the case recover, it will be my first recovery after two deaths in former years." This child recovered.

Dr. Van Horn, of Farragut, reports four cases: "Treated three with antitoxin, recovered; one not treated died; tested with cultures."

Dr. Milnor reports "four cases treated in the contagious ward of the hospital in October, 1896. Average age, eight and one-half years. Treated three by Mulford's serum of antitoxin of diphtheria, one by Parke, Davis & Co.'s. Three were treated at an early stage, one late. Average time in the hospital, ten days. No complication. Four recoveries. Temperature subsided in from twenty-four to forty-eight hours. Diagnosis confirmed by culture."

Dr. H. G. McCormick states: "I have treated with antitoxin twenty-four cases, ranging in age from two to thirty-two years. In three of them I gave a second dose. The

posterior nares were involved in three cases; one had croup. All recovered. Paralysis of the muscles of deglutition followed in two cases. In no instance was the injection given longer than four days. The antitoxin was not wholly depended on, other remedies being used. In all of the cases, marked control of the disease was noticed within eighteen hours. There were no abscesses following the injections in any instance. Most of the cases were treated in the hospital, and cultures were made in all, with the result of finding the Klebs-Loeffler bacillus."

Dr. A. P. Hull states, November 9: "I have used antitoxin of diphtheria in nine cases of diphtheria and three cases of croup. I saw the first case on the fourth day, an exceedingly bad one, gangrenous in character, with nasal complications; the dead and blackened uvula dropped off with the membranous exudate. I used injections of Behring's No. 2 antitoxin twice in twenty-four hours. The child recovered, with a slow convalescence.—I saw the second case on the third day; the membrane had extended into the nose. I used antitoxin; patient began to improve on the fifth day, and made a rapid recovery.—The third case was seen on the fifth day; membrane extended into the nose. Next day the glands were very much swollen. No improvement after injection. Death on the eighth day.—The fourth case I saw on the fourth day; membrane covered the tonsils, palate, and throat. After injection of antitoxin, patient began to improve, and on the sixth day made a rapid recovery.—The fifth case was seen on the second day; membrane was confined to the tonsils, and cleared off about the fifth day, followed in a week by paralysis of the throat, which lasted a month.—The sixth case I saw on the third day; membrane covered tonsils, throat, and palate. Recovery.—The seventh and eighth cases were injected on the third day; membrane was confined entirely to the tonsils. Both recovered, though one had a protracted paralysis.—The first case of croup was injected on the third day, and intubated at the same time. After remaining in the throat forty-eight hours, the tube was removed, with membrane attached; then replaced for five days. Patient recovered, with aphonia lasting six weeks. The second case of croup was in a diphtheritic family; injection was made within thirty-six hours, and complete recovery ensued in four days. The third case was similar to the second, but the injection was given twelve hours later; patient recovered.

I have used Mulford's, Behring's, and Parke, Davis & Co.'s serums, and report my histories from memory."

Dr. Charles Youngman reports five cases, with two deaths. The first patient, aged fifty-five, contracted the infection from clothes in a pernicious case. Gangrene and sepsis were present. Antitoxin was used twice, on the fifth day after infection. Death occurred on the tenth day, from exhaustion. The second case, a boy, aged ten, who received the antitoxin twenty-four hours after his illness began, died twelve hours later. In the third case, a boy of eight years, the antitoxin was injected thirty-six hours after inception of the disease; result, membrane dissolved on third day, and patient recovered. The fourth case, a girl aged six, was treated with the antitoxin twenty-four hours after infection, and was well by the sixth day. The fifth case, aged twelve, was injected forty-eight hours after diagnosis; cured on seventh day.

Dr. Robinson, of Morris, Tioga County, says he has had in two years 307 cases of diphtheria, using mild chloride of mercury and peroxide of hydrogen in the atomizer every two hours. For the malignant cases and those with croup he had no reliable remedy until he used the antitoxin of diphtheria. "My first two cases," he writes, "on whom the antitoxin was tested, were pronounced hopeless by other physicians. They were sixteen and eleven years of age respectively; temperature ranging from 104° to 105°; exudation nearly filling the throat. As I had only one bottle of antitoxin, I used it on the worst case, with the result that the face became flushed, in six hours large pieces of membrane were dislodged, and in twelve hours the temperature had fallen to 101°. Convalescence in two days was accompanied by aphonia, loss of hearing, and ocular paralysis. I was not able to secure any more antitoxin, and the second case died in twenty-four hours; I believe antitoxin would have saved it. Since then I have depended entirely on antitoxin in all serious cases, forty-seven in all. Two of these have been pronounced incurable by other physicians. I believe that if used in time antitoxin will cure every case of diphtheria."

Dr. Gardner, of Scranton, writes: "I have not had a large experience with diphtheria antitoxin, nor are my statistics very convincing on paper, but the practical application has given me great confidence in the remedy. I had lost all confidence in the older remedies, and, while cases recovered,

I do not believe the remedies applied had much if anything to do with the recovery. I now go to a case of diphtheria with great confidence. I report as follows: Pharyngeal diphtheria, six cases, one death; laryngeal diphtheria, seven cases, three deaths. The laryngeal cases were seen in consultation when the stenosis was severe. They were intubated, and antitoxin used as soon as possible."

Dr. John A. Klump writes: "With reference to my limited experience in the use of diphtheria antitoxin, I can report results only in about ten cases of my own. In every case where the serum was injected early, there seemed to be a favorable effect produced. The membrane seemed to melt away rapidly in the course of from thirty-six to forty-eight hours. In only one case could one claim almost positive evidence of the favorable influence of the serum; that was in a girl aged eight years, who had a mild form of faucial diphtheria which, under the bichloride treatment, disappeared in three days; on the fifth day diphtheritic croup developed, and breathing became so difficult that intubation offered to my mind the only hope of saving the patient. The parents absolutely refused to allow the employment of a tube. As a faint hope I injected a dose of the antitoxin, and left the child, as I supposed, to die, for she was cyanosed, pulse 160, and throwing herself about on the bed, struggling for air. The following morning, twelve hours after injection, the child lay unconscious, quiet, and in a cold sweat, the breathing continuing about the same as on the previous evening. On the second day, thirty-six hours after injection, she began to breathe better, and from that time on recovered rapidly, so that in a week she was quite well. I always use the serum in connection with intubation, and it seems to shorten the time required for wearing the tube. There have been cases among my own patients and those of others that I have seen where the effects of antitoxin were not apparent."

Dr. Flanagan, of Ralston, reports twenty-nine cases treated with bichloride and peroxide of hydrogen, with fourteen deaths, and fourteen cases treated with anti-diphtheritic serum, who recovered. He quotes several cases in full, demonstrating that the epidemic was of such a malignant character that a large percentage of deaths would have resulted under the old treatment. He says: "I will give my experience with twenty-nine

cases treated with bichloride and peroxide of hydrogen before I used the antitoxin. Several years ago I was in the midst of an epidemic of diphtheria. Mr. P.'s family of six children, ranging from two to seventeen years, were attacked. After the first night we buried one every night for five consecutive nights, with the best of consultants; only one recovered of that whole family. The mother gave birth to a child during this sickness, and the infant had umbilical invasion and barely recovered. There were two cases in Mr. H.'s family; one died, as well as a babe one week old; the exudate extended into the larynx, producing croup. Mr. E.'s family—self, wife and nine children—all recovered, except three who died of croup. In September, 1896, I had nineteen cases of diphtheria. Five were treated without antitoxin; four of these were mild, but Pearl, aged eleven, weighing 104 pounds, who had never been sick, had headache, vomiting, high temperature, after twenty-four hours exudation on tonsils and fauces, which increased daily, and on the fourth day the nares were involved, cervical glands enlarged, and cellular tissues implicated; fifth day, croupy; sixth day, general toxemia, pallor, feeble heart-action; on the eighth day she died. A brother, aged four, had the same symptoms, with characteristic diphtheritic membrane upon both tonsils,—on the second day, the nose and cervical glands were involved, with purulent discharge, nasal obstruction, laryngeal stenosis, pulse 140, respiration 40; on the fourth day I called Dr. Nutt in consultation, who injected into the dying child Behring's antitoxin No. 2 at 4 P.M., remarking: 'If that child gets well I will have lots of faith in antitoxin of diphtheria.' At 10 P.M. respiration was improved, pulse 120; and in three days the throat was clear of exudates and the child saved, though he was not fully convalescent for a month. A fortnight later the boy's aunt, who had nursed all the children, had diphtheria, with the usual symptoms, exudate extending rapidly. After forty-eight hours, the pulse being 122 and the heart-action weak, I injected Behring's No. 2 antitoxin; in addition gave one-thirtieth of a grain of strychnine three times a day. Patient stated: 'From the time antitoxin was used my throat grew no worse, but the exudate did not come off for ninety hours. There was a grayish exudate like an oyster with holes in my throat.' She convalesced slowly, had aphonia for two months, with paralysis of muscles of deglutition, and general exhaustion. I believe she would have

been benefited by a second injection. Another child in this family, a boy, was attacked with the usual symptoms of diphtheria; in six hours I gave him an injection of Behring's antitoxin No. 2, and in twenty-four hours he was convalescing. The balance of the cases convalesced immediately after the use of the antitoxin. When this is given within six to twelve hours after invasion, I have no trouble. Summing up: of twenty-nine cases treated without antitoxin, I lost fourteen, or forty-eight per cent.; and in fourteen cases in which antitoxin was used, there were no deaths, and no one now fears diphtheria among us."

My own experience is gratifying. I have treated twenty-three cases with antitoxin, and lost only one, a child of six months; this patient improved for four hours, and then became cyanosed, indicating heart-failure, probably due to the septic impression upon the cardiac centres. This was not due to the age of the child, as another child of the same age, that had not only exudation upon the tonsils, but a patch upon the neck three by five inches (tested by cultures), recovered in four days. Where the antitoxin is used within thirty-six hours of diphtheritic invasion, there is a gradual fading away of the exudate, with immediate return of appetite and strength.

I formerly used Behring's preparation, then Mulford's, but at present prefer that made by Parke, Davis & Co., as it is held in bulb tubes that are smaller in bulk, more convenient for use, apparently more aseptic than the ordinary packages with corks, and the serum itself gives less pain in injecting.

In recent cases I have found 1000 units ample for the average case. Some require a second injection; I am governed in this by the elevation or depression of temperature. While confident of the ability of antitoxin to destroy the bacilli in the circulation, I prefer to use 1:2000 bichloride locally, or by spray, with calomel, until it acts freely on the secretions, in order to prevent reinfection. The State Board of Health provides, free of expense, bacteriological examination of exudates of diphtheria, but, unfortunately, there will be so much valuable time lost that the delay may prove fatal in many cases. I am so fully impressed with the value of antitoxin of diphtheria from my own experience, independently of that of others here presented, that I believe in case of failure there is either an insufficient amount injected, or the preparation is not reliable. In all cases

which present the ordinary signs of diphtheria, I use the antitoxin, and then prepare my culture for confirmation of diagnosis.

In conclusion permit me to present the experience of physicians in this vicinity, which, in a word, is this: One hundred and eighty cases treated by antitoxin, with six deaths—an experience eloquent in unparalleled results.

#### *THE DURATION OF ACUTE GONORRHEA UNDER TREATMENT.\**

BY H. M. CHRISTIAN, M.D.,

Chief of the Genito-Urinary Dispensary, University of Pennsylvania; Adjunct Professor of Genito-Urinary Diseases, Philadelphia Polyclinic.

The subject of this paper was suggested to my mind by a discussion recently held with several medical friends, all of whom are engaged in general practice, regarding the length of time required to cure acute, uncomplicated gonorrhea. It was a matter of great surprise to me to learn that the unanimous opinion of all present, myself excepted, was that gonorrhea, under ordinary circumstances, should generally be cured in about three weeks. This statement, so utterly at variance with my own experience, induced me to make some further inquiries among physicians engaged in general practice, regarding this matter of the duration of acute urethritis, which investigations have led to the conclusion that about nine out of ten of all physicians, other than special genito-urinary surgeons, claim to cure the disease in from three to four weeks.

Now, in view of the fact that surgeons engaged exclusively in genito-urinary work, and therefore having the most extended clinical experience in the treatment of acute gonorrhea, have never claimed such uniformly brilliant results, it would seem very evident that many if not all of these rapid cures must be set down as of rather doubtful character, to say the least. The writer would not for one moment be understood as questioning the honesty and good faith of those claiming to cure gonorrhea in three weeks. There can be no doubt that these gentlemen are perfectly sincere in their belief that their cases are really cured.

It is hardly necessary for me to call your attention to the innumerable drugs and plans of treatment, highly extolled in eulogistic articles, in our weekly medical journals, all claiming to cure gonorrhea in from two to

\* Read before the American Genito-Urinary Association, at Atlantic City, June 3, 1896.

three weeks. Methods claiming to cure in from six to eight weeks are not in vogue, and are therefore not published.

The philosophy of most of these phenomenally quick cures is based, as a rule, upon the early employment of same astringent injection, causing, as pointed out by Taylor, a rapid and early onset of the mucous terminal period of the disease, the chief characteristic of which is a thin watery discharge which might readily pass unnoticed by a careless or unobservant patient.

Now, as a matter of fact, the great majority of these cases are not cured at all, although the attending physician, enthusiastic to the highest degree over the presumed success of his "sure and quick" remedy, may be perfectly honest in assuming such to be the case.

It seems to me that the great difficulty in this whole matter, and the cause of much misunderstanding, lies in the fact that the average general practitioner of medicine is entirely unacquainted with the means of determining when a case of gonorrhea is in reality cured. Absence of discharge at the meatus too often means, to him, cure of the disease. No examination of the urine for clap-shreds is made; in fact, very little seems to be generally known as to the importance of such examination.

If what our gynecological brethren claim in regard to the longevity and depredations of the gonococcus be true, it would seem to be a matter of the utmost importance that we, as genito-urinary surgeons, should do all in our power to correct this widespread notion that gonorrhea is a simple disease, easily cured in from two to three weeks, provided the special formula of Dr. "A" or Dr. "B" be employed early in the case. For my part I believe, with Taylor, that gonorrhea may be, and very often is, one of the most formidable diseases that can attack man.

What, then, is the duration of acute uncomplicated gonorrhea? Finger states that cases of acute urethritis with no unusual symptoms last from five to six weeks. He allows two weeks for the increasing stage, one week for the stationary, and two to three weeks for the mucous terminal period. He further states that cases with a short incubation and rapid onset do not last as long, all things being equal, as those with a long period of incubation. In the opinion of R. W. Taylor, a man should consider himself very lucky to be cured of gonorrhea in from six to eight weeks. Keyes places the average dura-

tion at from four to six weeks. Brewer\* makes a significant statement regarding this matter. Referring to an article previously written by himself upon the rapid cures produced in a series of cases by the use of bichloride of mercury, he here states as follows:

"Experience in the treatment of urethral disease has taught me that the simple cessation of discharge by no means indicates a cure of the disease; and I am prepared to say without the slightest hesitation that it is my belief that, had a careful and thorough examination been made in each instance at the time when I reported the cessation of all discharge, not one case of my three series of cases would have failed to show unmistakable evidences of an uncured urethritis."

Dr. J. William White gives the duration of acute urethritis as from four to six weeks. Dr. Martin thinks a case fortunate that is cured in eight weeks.

In presenting to your consideration the following statistics taken from the case-book of the Genito-Urinary Dispensary of the University of Pennsylvania, as bearing upon the matter, I thoroughly appreciate how entirely unreliable and unsatisfactory statistics taken from dispensary records are apt to be. The tendency of our hospital patients to wander around from one institution to another is well known, and allowance must always be made for this habit in forming any conclusions from a study of hospital records.

In conducting the investigations as to the duration of acute uncomplicated gonorrhea, all cases were divided into two classes: first, those suffering from their first attack; and second, those who have had one or more previous attacks.

In the first class, the following points in the histories were noted: the time at which they voluntarily stopped treatment, and the condition of discharge at last visit. In this class I have carefully compiled notes of 117 cases. Of these, 10 paid only one visit to dispensary, 12 stopped treatment at the end of one week, 16 at the end of two weeks, 21 at the end of four weeks, 11 at the end of six weeks, 2 at the end of seven weeks, 29 at the end of eight weeks, 16 at the end of ten weeks. The note made at last visit in regard to discharge is as follows: Thin mucous discharge in 28 cases; morning drop in 52; cured, 17; condition unknown, 10.

The discharge in all of these cases con-

\* Morrow's System of Genito-urinary Surgery.

tained gonococci; total urethritis developed in 95 cases. All the patients, as far as could be determined from their own statements and from their general condition, took good care of themselves and carried out the prescribed treatment to the best of their ability.

No complications were noted.

It is, of course, impossible to draw any exact inference as to the duration of gonorrhea from figures such as these. Approximate results only can be deduced, but even these have a very decided value. For example, it is of course impossible to say what was the result in the ten cases that made only one visit to the dispensary. The probabilities are that in a certain proportion of these cases the discharge was so much moderated by the first treatment advised as to cause no further inconvenience to the not over-particular patient.

The most important point to which I desire to call attention is that the discharge persisted four weeks and over in seventy-nine, or two-thirds of all the cases. Of these seventy-nine cases, forty-seven were under treatment from seven to ten weeks.

In the second series of cases, where there was a history of one or more previous attacks of gonorrhea, in addition to the points noted in the preceding series, inquiry was made as to the duration of the former attack according to the patient's own statement.

In this class notes have been made from the records of seventy cases. The length of previous attack is stated by the patients to have been as follows: in 8 cases, one week; in 8 cases, two weeks; in 14 cases, four weeks; in 20 cases, eight weeks; in 20 cases, eight to ten weeks.

The length of time they remained under treatment at the dispensary for present attack is noted as follows: 4 cases made one visit only, 8 cases discontinued treatment in one week, 12 cases discontinued in two weeks, 4 in three weeks, 10 in four weeks, 17 in eight weeks, 15 in ten weeks.

The above series of cases is doubly interesting as compared with the first, by reason of the fact that, in addition to an approximate idea of the duration of the attack for which they were treated at the dispensary, we have the patients' statements as to the duration of their former attack, which is noted as having lasted from eight to ten weeks in forty cases. From four to ten weeks is the time noted in forty-two cases as the duration of treatment at the dispensary.

Taken together, these two series include

the records of 187 cases of acute gonorrhea. Of these, 17 remained under treatment at the dispensary until they were pronounced cured. Of the remaining 170 cases, 121 were under treatment from four to ten weeks.

The most valuable and instructive of all the records are those referring to the cases remaining under treatment persistently until all clap-shreds had disappeared from the urine and they had been pronounced cured. That these represent a very small proportion of the total number reported is very true; and this fact is undoubtedly due to the well known tendency of all patients to take upon themselves the responsibility of determining when they are cured. This series of cases, seventeen in all, includes medical and dental students and married men, all anxious to be permanently cured, and therefore willing to continue treatment until pronounced cured. The date of cure in all these cases is put at the time at which the urine was first clear and free from clap-shreds containing pus. The length of time required to cure the disease was as follows: four weeks in 3 cases; six weeks in 3 cases; seven weeks in 2 cases; eight weeks in 4 cases; ten weeks in 5 cases.

I have every reason to believe that, as all these patients were particularly desirous of getting well, no indiscretions were indulged in by them that would in any way help to prolong their attack. Gonococci were present in the discharge in every case. All but three had involvement of the entire urethra. Where the anterior urethra alone was involved, the cases were cured in about four weeks. It will be noted that the duration of the disease was over six weeks in ten of the cases.

Although the treatment of acute urethritis does not lie within the scope of this article, nevertheless it might perhaps be of some interest to briefly mention the line of treatment pursued in all of these patients.

Four different methods were employed: internal medication alone; internal treatment combined with use of hand-injections; irrigation of urethra alone; and irrigation of urethra combined with internal treatment.

From a careful study of the results obtained by these various methods of treatment, one fact is very evident, namely, that those patients did best and were most quickly cured upon whom daily irrigation of the urethra was practiced, together with the internal administration of oil of sandalwood and balsam of copaiba. This line of treatment was pursued for two weeks, and followed by the

use of an astringent hand-injection of either sulphate of zinc and acetate of lead, each three grains to the ounce of water, or sulphate of copper or chloride of zinc, one-half grain to the ounce. The remedy used in most of the irrigations was permanganate of potash, beginning with a solution of the strength of 1 to 4000, increasing every other day in strength up to 1 to 500. It was found that irrigation alone could not be depended upon to absolutely cure the disease, but that it did produce a marked lessening of the profuse discharge of the acute and stationary periods, and bring the case in a short time into the mucous or declining stage, where the use of an astringent hand-injection was all that was requisite to complete the cure.

In all cases where the discharge persisted over ten weeks the condition was regarded as chronic, and the urethra was explored for the presence of soft or granular strictures. Examination of the rectum was also made, to discover if possible, whether there was any affection of the prostate gland or seminal vesicles. When these were found to be affected, massage, stripping the vesicles, and hot rectal douches were employed, no urethral treatment whatever being applied in such cases.

The following conclusions are presented, as a result of the study of statistics, just given:

First: That gonorrhea is a much more prolonged and serious affection than it is usually considered to be by general practitioners of medicine and by the laity.

Second: That in two-thirds of all cases uncomplicated the period of time necessary to obtain a complete cure is from six to ten weeks.

Third: In that small proportion of cases where the entire urethra does not become involved, the disease being confined entirely to the anterior urethra, we can, as a rule, expect complete recovery in about four weeks.

Fourth: The necessity of impressing upon the profession in general the importance of making examinations of the urine before deciding that an attack of gonorrhea is positively cured.

---

#### *CLINICAL NOTES ON THE ANALGESIC EFFECT OF LACTOPHENIN.*

BY CHAS. S. POTTS, M.D.,

Instructor in Nervous Diseases at the University of Pennsylvania; Assistant Neurologist to the University Hospital.

Lactophenin, the most recently introduced of the coal-tar products having antipyretic and analgesic properties, while in use in Ger-

many since 1894 in the literature of which place many favorable reports of its action are to be found, has apparently not become well known to the profession of this country.

Chemically it is a phenetidine derivative, containing lactic acid in place of the acetic acid constituent of phenacetin. It is but slightly soluble in water, and is practically tasteless.

The writer's experience has been limited to its action as an analgesic. The number of cases reported is not large, but still it is sufficient in number and variety to show that lactophenin is a valuable agent for the relief of pain.

CASE I was a man sixty-five years of age, who for some time had been a sufferer from neuralgia involving the trigeminal nerve. By the use of lactophenin in five-grain doses four times daily, the pain entirely disappeared in a couple of days.

CASE II, a young man aged twenty-two, had had constant pain over the left eye, with violent exacerbations in the afternoon, for two years past. He said that nothing he had tried had any effect. Lactophenin in seven-grain doses every four hours relieved the pain, which, however, returned when the administration of the drug was stopped. The patient was permanently cured with large doses of quinine.

CASE III.—Patrick S., aged twenty-seven, had been suffering for three days before coming to the clinic with a violent neuralgia affecting the branches of the trigeminal on the right side. He had a number of bad teeth. Three doses of eight grains each, of lactophenin, taken every three hours, completely relieved the pain.

CASE IV.—Eight grains every three hours were given to a woman suffering from neuralgia of the trigeminal nerve. The next day she reported that the pain had ceased.

CASE V.—A patient with neuralgia of the supra-orbital branch of the ophthalmic nerve was given eight grains every three hours, for two days, without any beneficial results.

CASE VI.—John D., aged thirty-five, for a year past had been troubled with a severe sciatica. Ten grains every four hours relieved the pain for a while, but it finally returned. All other modes of treatment have since been tried in this case without result.

CASE VII.—Mrs. M. F., aged fifty, was given five grains every three hours for severe pain in the right side of the face and ear, due to an epithelioma of the larynx. This dose relieved the pain, but she complained that it

made her sick at the stomach. The same dose of phenacetin was then tried, but it did not relieve the pain so well.

CASE VIII.—H. S., aged sixty-four, complained of most intense continual pain involving the entire head. This was afterwards found to be due to an alveolar abscess. The patient also had interstitial nephritis. Lactophenin gr. iv, p. r. n., relieved the pain, although it was necessary finally to increase the dose to eight grains to obtain results.

CASE IX.—Mrs. S., aged forty-five, has a family history of migraine on both sides, and has been subject to headache since a child. Her attacks begin with a feeling of chilliness, followed by severe shooting pains all over the body, this in turn being succeeded by violent headache of the ordinary migraine type. By taking four grains of lactophenin when she felt an attack coming, she was generally able to stop it. At times it was necessary to repeat the dose in an hour.

CASE X.—Mrs. W., aged thirty. Family history of migraine on mother's side. Patient has had attacks since she was sixteen years of age. Nothing except antipyrin ever had any influence in stopping an attack, until she was given five grains of lactophenin p. r. n. This, so far, has always aborted the attack.

CASE XI.—John D., fifty-two years of age, gave a history of having been subject to muscular rheumatism, usually in the muscles of the back, for the past seven or eight years. Lactophenin, gr. x, was prescribed, to be taken when he felt the approach of an attack. One or two doses taken thus have always aborted the seizure.

CASE XII.—Kate G., aged forty-five, had severe pains and stiffness in right sternomastoid muscle for two weeks. The muscle was also tender. Lactophenin, gr. x every four hours, was ordered. Three days later she reported herself very much better. At her third visit, five days after the first, she was entirely well.

CASE XIII.—M. O'N., aged thirty-nine, a chronic sufferer from locomotor ataxia, complained very much of severe shooting pains in the chest and legs. He was ordered eight grains of lactophenin, to be taken every four hours. Three days later he reported that the pains had ceased. Since then (six months ago), he has been able to control the pain with this remedy.

CASE XIV.—W. B., aged thirty-five, with locomotor ataxia; complained of severe darting pains in the legs. Lactophenin, gr. viii p. r. n., always relieved the condition.

In addition to the above the remedy was also given to four victims of ordinary headache, who did not return and were presumably relieved.

It will be seen that the drug was administered to five cases of neuralgia involving the branches of the trigeminus, four of whom were relieved; to one case of severe sciatica, that was benefited for a time; to two cases of severe reflex pain due to irritative conditions elsewhere; to two cases of migraine, two of muscular rheumatism, two of the characteristic pains of locomotor ataxia, all of whom received benefit from the use of the drug; and to four cases of simple headache presumably benefited.

Of the fourteen cases that we have been able to follow only one (Case V) entirely failed to be benefited.

In an outdoor clinic, of course it is not possible to study the influence of a drug upon physiological functions of the body, but it will be noticed that the lactophenin was administered freely to patients of all ages and conditions, and in none, excepting Case VII (who said it caused disturbance of the stomach), were any bad or unpleasant effects noted or complained of. In one case (Case VII) phenacetin failed where lactophenin succeeded. It would thus seem safe to say that lactophenin is a safe and efficient agent for the relief of pain.

---

*SUCCESS OF THE VIENNA TREATMENT  
IN AFFECTING THE PASSAGE OF  
A SET OF FALSE TEETH.*

---

BY HENRY L. WILLIAMS, M.D.

Service of Dr. Edward Martin, Howard Hospital.

---

On returning to the Howard Hospital at about 11 o'clock on the night of July 18, 1896, an officer of the Salvation Army was found waiting in the dispensary in great disquietude of mind because of having swallowed his false teeth.

The history elicited was as follows: Arthur W., aged forty-two, married, the father of six children, had been addressing a meeting of the Salvation Army during the evening. At the end of his address, being exceedingly warm, he had taken a glass of ice-water, thrown back his head, and started to drink rapidly. With the first swallow he felt the plate which he wore in the roof of his mouth pass back into his throat. He made every effort to dislodge it by coughing and retching, but without result. Becoming fright-

ened, he then ran into the adjoining room, where his wife was in waiting. She was informed of the situation in a word, and immediately pounded him vigorously on the back between the shoulder-blades. Within a few seconds he felt the teeth begin to pass down the esophagus, with a sensation of scraping, followed by a feeling of entire relief. This was soon after 10 o'clock. He then went into the office of a physician close at hand, and was given two large pieces of raw apple to swallow in order to render certain the fact that the foreign body had passed into the stomach and was not lodged at any point in the esophagus. These he swallowed without difficulty. He was then referred to this hospital, and came at once.

Mr. W. is of German descent, a stone-mason by trade, rather short and thick set, and of powerful frame. He has always enjoyed absolute health. The plate was described as containing the two central incisors and the left first molar, and having at each end a small metal "hook" which clasped the base of the adjacent tooth and held it in position. The accompanying drawing was sub-

quences, was very great. The man was strongly advised to remain quietly in the hospital during the night, and await the visit of the surgical chief in the morning. This he declined to do. He also refused to take an emetic which was proposed with the hope that the body which had been swallowed might be ejected and thus all further danger eliminated. He then said that he would go home and just trust in the Lord, and, in case any symptoms developed, would at once return to the hospital.

I endeavored to show the man that if he neglected any measures that might aid in preserving his safety it would be most foolhardy, and advice was given him to at once drink copiously of lukewarm water and mustard, and to eat only mashed potatoes for the next forty-eight hours.

The patient returned the next afternoon in the best of spirits, with the following story:

On reaching home a little before midnight he at once took a pint and a half of warm water containing a tablespoonful and a half of Coleman's mustard. This failed to nauseate him in the slightest, but served to put him

2

3

1. Two upper incisors. 2. Hooks to hold the plate. 3. First molar. 4. Body of plate.

sequently made from the plate, and accurate measurements taken, as follows: The greatest length from tip to tip was  $1\frac{3}{4}$  inches; the greatest width three-fourths of an inch. The hook which partly encircled the base of the left second bicuspid was made of hardened gold, rather slender and delicate, and projected one-quarter of an inch from the plate. The hook upon the right side, also of gold, clasped the base of the right canine tooth; this was likewise slender and rather sharp, but projected only one-eighth of an inch.

It was carefully explained to the patient that it was quite likely such a body would not pass the pylorus; that in case it did pass, the danger of its becoming caught at some portion of the intestinal tract and causing obstruction or perforation, with fatal conse-

quences, was very great. At 2 A.M. he awoke and ate a large plate of mashed potatoes which his wife had prepared for him. He then went to sleep at once, and woke next at 9 A.M., and again ate heartily of mashed potatoes. After this he once more slept for an hour, and soon after ten o'clock dressed and lay quietly upon the lounge. Shortly before noon he felt what he described as a "scratching sensation" which he located in the left iliac fossa over the line of the sigmoid flexion of the colon, attended with an impulse to evacuate the bowels. This he did, and obtained simply a normal stool. In about ten minutes he once more felt the call of nature, and this time discharged a large mushy mass, in which the teeth were discovered. In the mass immediately surrounding the plate were found

also large pieces of shaved beef, which had been eaten for supper on the previous night, and which, probably, quite as much as the potatoes, had protected and coated over the body in its passage through the intestines.

The man was in the best of spirits over his escape, and removed the plate from its old accustomed place, that it might be inspected, measured and drawn.

---

*EUCAINE HYDROCHLORATE AS A LOCAL ANESTHETIC IN HYPERTROPHIC RHINITIS.*

---

By LEWIS S. SOMERS, M.D.,  
Of Philadelphia.

---

The new chemical compound, eucaine hydrochlorate, appears from the statements of German investigators, to be destined to supplant cocaine, especially on account of its decided action as a local anesthetic and the results so far obtained showing that, although the drug is toxic in large doses, still when compared with the cocaine salt *cateris paribus* it possesses much less toxic effects. From recent reports of its anesthetic action in eye surgery the majority of investigators concede eucaine to be of more value than cocaine.

I have recently used the drug in a series of cases of hypertrophic nasal catarrh, in place of cocaine, to produce anesthesia of the enlarged turbinals, so that reduction in their size by cauterization might be effected. A four-per-cent. solution of eucaine hydrochlorate in distilled water was used, this corresponding to the strength of cocaine solution previously employed for that purpose. The drug was applied to the turbinated bodies in the same manner as cocaine, by saturating a cotton plug with a definite quantity of the solution and applying it to the part to be operated on until anesthesia was completed. The cauterization was effected by means of chromic-acid crystals melted on the end of an appropriate applicator by means of the alcohol lamp. The results obtained can better be expressed by comparing the effects of the two drugs *seriatim*.

Cocaine usually produces its anesthetic effects in the nasal cavity in from three to five minutes, anesthesia continuing for twenty minutes to half an hour. In the series of cases in which eucaine was used, anesthesia was not complete until eight or ten minutes had expired, and the loss of sensibility remained about twenty minutes. When an excessive amount of cocaine solution is used in the nares, it occasionally flows backwards

into the naso-pharynx, producing a very uncomfortable sensation of numbness in that region. It was noticed that this did not occur so markedly when eucaine was used, probably because of its slower anesthetic action.

Eucaine causes hyperemia of the mucous membrane when locally applied. This action is directly opposed to that of cocaine, and renders the drug of little value when the turbinal tissues are much hypertrophied, as the cauterizing agent cannot be introduced into the nasal cavity without injuring the septum. This action of eucaine in producing a temporary local congestion militates greatly against the use of the drug in active inflammatory conditions, but may possibly be obviated by using equal parts of eucaine and cocaine, as recommended by Berger. Dr. Reichert, of Berlin, has used eucaine in the throat and naso-pharynx, and claims that aside from its anesthetic action, it is harmless in medicinal doses, not rapidly and suddenly affecting the heart as does cocaine.

This over-sanguine enthusiasm for the drug on the part of some observers should be carefully considered before it is used very freely, as eucaine is a poison similar to cocaine, but possessing the great advantage of being decidedly less harmful to the organism when used in the same doses. Dr. Reichert also claims that eucaine influences a curative action in diseases of the Schneiderian mucous membrane, independent of its anesthetic properties. Another advantage which the drug possesses over cocaine is that it may be kept for an indefinite time in solution with sterilized water, one part to ten. The solution may be repeatedly sterilized by boiling, without impairing its anesthetic properties.

Of minor importance is the fact that the price of eucaine is less than that of cocaine.

---

*THE USE OF ICHTHYOL AS A LAXATIVE.*

---

GUNSBURG has reported the use of this treatment in fifty women suffering from various inflammatory affections of the genitalia, accompanied by constipation and dyspepsia. The ichthyol was given in pills of three grains once, twice, or thrice a day. The result was that the constipation was overcome without any colicky pain or diarrhea, the appetite improved, and the pain in the abdomen decreased. As the taste of the ichthyol is disagreeable, Gunsburg suggests that it be given in keratin-coated or enteric pills.—*Bulletin Générale de Thérapeutique*, Oct. 23, 1896.

### THE NECESSITY OF USING PURE DRUGS.

It would seem almost unnecessary to call attention in this journal to the necessity for the physician who prescribes his own medicines, or who permits the pharmacist to dispense them for him, to use the purest and best medicinal agents which the drug market can possibly afford; yet we have recently come in contact with a number of instances where physicians or pharmacists, with a false idea of economy and business foresight, purposely purchased low-grade crude drugs or medicinal preparations, thinking that thereby they would be pecuniary, if not moral, gainers. To us such an attempt seems to be a manifestation of the most short-sighted policy. The physician's reputation depends very largely, if not entirely, upon the success which he has in the treatment of the patients who come to him for his skill, and in many instances this skill in diagnosis and therapeutics is entirely counteracted by an impure or worthless drug. The great majority of surgeons—whose results are perhaps more manifest to the eye of their patients and

their friends than are the results obtained directly by the physician—always see to it that the instruments which they employ are made of faultless steel, that they are neither too sharp nor too dull, and that the dressings are adapted to the purpose of aiding most effectually in the rapid healing of the wound.

Perhaps the short-sighted policy to which we have referred is most common among persons in country districts who, for the sake of saving a very few cents on large orders of medicinal preparations, frequently obtain drugs which are not entirely reliable. In one particular instance which has recently come to our knowledge, a large firm of wholesale druggists found that they had a line of drugs which they did not consider perfectly reliable, and which they sold to another wholesale house, who immediately advertised them at low prices to the greater part of the medical profession in country districts, and, we regret to say, found a rapid sale for drugs which the first house had not been willing to sell to physicians or retail druggists, lest their reputation be tarnished.

The use of such preparations by the physician can be summarized in a few words: Poor drugs bring poor results; poor results bring a poor reputation; and a poor reputation brings little money.

### THE VALUE OF CLIMATE IN CASES OF GENITO-URINARY TUBERCULOSIS.

We are so accustomed to look to climate for beneficial influences in persons suffering from pulmonary tuberculosis that we are perhaps apt to overlook the advantages that can be afforded by this method of treatment in tuberculosis of other important organs, and, as a result, give a patient an unfavorable prognosis as to his condition, or insist that surgical measures shall be instituted for the removal of the infected organ.

In many cases, no doubt, surgical interference is the best treatment, since it not only removes the diseased area but to a great extent protects the rest of the body from a secondary infection. On the other hand, it should not be forgotten that in far advanced tubercular disease of the genito-urinary apparatus surgical interference often appears, by breaking down protective walls of lymph, to throw open the entire system to general tubercular infection, so that the patient more speedily succumbs to tuberculosis than he would had the original point of infection been left alone.

In this connection it is interesting to note the conclusions which have been arrived at by Dr. J. C. Munro, of Boston, in a paper contributed to the proceedings of the last meeting of the American Climatological Society. In order to obtain some definite idea as to the value of climate in genito-urinary tuberculosis, he sent out a number of letters to physicians inquiring as to their experience in this matter, and, out of seventy-five responses, obtained fifty which are more or less replete with valuable data.

The result of this collective investigation by Dr. Munro seems to prove, according to his conclusions:

1. That genito-urinary tuberculosis is benefited by climatic treatment.

2. That these patients should be sent to salubrious climates in the early stages of their disease, more frequently than has heretofore been the custom, and that moderately dry and equable mild climates are suitable for the majority of patients, the high and cold climates being reserved for the few.

Without doubt, the advantages which accrue to the patient under these circumstances are more largely due to the general improvement in his health and hygienic surroundings than to any direct influence which the climate may exercise upon the particular area of his body which is diseased. In other words, there is no direct effect produced, as there is in cases of pulmonary tuberculosis where the increased pulmonary exercise, the dry air and the avoidance of winds produce good results.

One point in this connection that is of very considerable importance—and one that is emphasized by Dr. Munro—is that excessive cold is particularly unsuited to those patients who, in addition to localized tubercular lesions, have some renal complication, since the chilling of the surface of the body greatly increases any difficulty of the kidneys and so aids in the progress of the general disease.

On the other hand, in the absence of severe heart and renal disease, it has been found that patients suffering from tuberculosis which is limited to the epididymis or the vesicles will in many instances do better in the climate of Colorado than in lower climates.

Again: exceedingly hot, dry climates are disadvantageous, particularly in prostatic and bladder troubles, because they are apt to impair the general health of the individual, and by the excessive action of the skin which they induce they cause a concentrated urine which distinctly increases the irritability of the bladder.

#### *THE DEGREE OF ANESTHESIA WHICH SHOULD BE INDUCED PRIOR TO SURGICAL OPERATIONS.*

Within the last few years we have called attention more than once, in the editorial columns of the *THERAPEUTIC GAZETTE*, to the importance of producing complete anesthesia before beginning an operation, particularly when chloroform is the anesthetic employed. In one of these editorials we emphasized our belief that fright has a very marked influence in increasing the danger which is ever present when chloroform is administered; and in another we pointed out that a possible cause of the large number of fatalities during the early part of the administration of chloroform might be traced to the fact that, combined with fright, there was sent to the heart a powerful reflex through the sensory and pneumogastric nerves as soon as the knife touched the skin of the patient or the surgical operation was begun. This is particularly apt to be the case under chloroform, because it would seem probable that early in the administration of this drug, while there may be some interference with consciousness and some benumbing of the ordinary sense of pain, there is not an abolition of tactile sense, but on the other hand rather a condition of excessive irritability of the nerves involved in this sense. Further experience has intensified our belief that our earlier views were correct, and the writings of leading surgeons and anesthetists the world over seem to point more and more to the correctness of this opinion. As an instance of this, we may quote the statements made by Dr. Hewitt, of London, in regard to this question. He points out that one chloroformist will work with light anesthesia, another with moderately deep anesthesia, and another with very deep anesthesia, but the success of Syme in administering chloroform appears to have been principally due to the almost invariable maintenance of a profound narcosis. He also points out, what the writer of this editorial has also pointed out in previous contributions to medical literature, that the very development of a profound narcosis tends to render the respiration regular and unhampered; whereas the administration of insufficient quantities of chloroform causes the respiration to be so irregular and uneven that it is impossible for the anesthetist during the course of a prolonged operation to make any accurate estimation of the quantity of chloroform which the patient is receiving. In other words, a part of the skill of an

anesthetist lies in his ability to give a sufficient quantity to induce deep anesthesia without giving enough to produce a condition of danger.

In many instances the surgeon is inclined to regard the early delays in the administration of an anesthetic as being a useless waste of time; and we have seldom administered an anesthetic for a surgeon, or watched its administration for one, without being impressed with the fact that his tendency is continually to hurry the anesthetist, with the result that the drug is often at first pushed more freely than the anesthetist himself believes to be proper. In our opinion, the most delicate stage in the administration of an anesthetic is during the period when the patient is passing from complete consciousness into unconsciousness, and, if the patient is well chloroformed, far less skill and knowledge is required to maintain the anesthesia in a condition of safety than was necessary earlier in the process.

---

#### THE PRESENT POSITION OF THE GONOCOCCUS IN GYNECOLOGY.

---

In a recent discussion in the Gynecological Section of the Sixty-eighth Congress of German Naturalists and Physicians, held at Frankfort-on-the-Main, Neisser called attention to the difficulty of formulating positive diagnosis as to the gonorrheal origin of disease of the adnexa. He states (*Archiv für Dermatologie und Syphilis*, bd. xxxvii, hefte 1 und 2) that it is quite otherwise in inflammations of the external mucous membrane the secretions of which escape externally. The mucous-membrane lesions show absolutely nothing which is characteristic of gonorrheal infection, and often the clinical history of the cases is not suggestive. In every suspected case the examiner should carefully inspect the urethra, the mucous-membrane immediately surrounding the urethral orifice, the cervical canal, and the orifices of Bartholini's glands. Moreover, rectal examinations should never be omitted. The vulva and vagina, often inflamed from the gonococcus in children, rarely show traces of involvement by this micro-organism in adults. Absolutely no characteristic alterations of the vulvar and urethral mucous membrane, such as papillomata, caruncles, and erosions, are excited by the gonococcus alone. Such lesions simply suggest a careful search for the gonococcus.

Although the culture methods as formulated by Bumm and Werthheim are extremely valuable, the diagnosis will mainly depend upon microscopic examination. This, when conducted by one thoroughly familiar with the appearance of the gonococci, is, with very few exceptions, absolutely reliable.

So-called "creeping" gonorrhea of women, caused by gonococci of lessened virulence, has no well proven existence. Even from the most chronic cases extremely virulent gonococci can be obtained. When gonococci are found, the diagnosis is established; if they are not found, it does not prove that they are not present, since they may lie in the deeper layers of the epithelium or be concealed in folds of the mucous membrane. Under these circumstances the examination should be repeated, and acute inflammation should be excited by application of irritating lotions. These repeated examinations should be made particularly when there is a persistent purulent discharge which is gradually increased from apparently insufficient causes.

Examination for gonococci is not only valuable from a diagnostic standpoint, but is also serviceable as a means of deciding when cure is complete. It is well known that gonococci may persist even after all subjective symptoms of inflammation have disappeared. These uncured cases—i.e., those free from clinical symptoms—are likely to become chronic and ultimately to develop ascending infection.

It is clear that treatment should have for its object not only the cure of subjective symptoms, but also the entire elimination of the gonococci. This end is attained by using medicaments which do not irritate the mucous membrane, which destroy gonococci, and which are not rendered neutral by chemical combination with albumin and mucin. The medicaments of choice are the salts of silver (argentin, argonin, argentum nitricum, actol, itrol), hydrargyrum, oxycyanatum, and ichthyol. The lotion employed must be brought in contact with every portion of the infected mucous membrane. It should be used as early as possible. Every effort must be made to prevent the infection from ascending.

Gonorrhea should be prevented by a careful bacteriological examination of the urethral discharges of men before they are allowed to marry, by similar repeated examination of prostitutes, and by a universal training of physicians in the various phases and manifestations of the disease and the proper method of searching for the gonococcus.

Saenger, taking up the subject of residual gonorrhea in woman, states that, after disappearance of the gonococci in the secretions, certain manifestations may remain. The period during which gonococci may persist is not known. It is evident, from examination of relatively fresh tubal and ovarian abscesses, that, in these closed spaces the gonococci do not long survive. It is possible they may disappear from the mucous membrane of the external genitalia, since, following gonorrhea, lesions are often found in whose discharges gonococci are not discoverable.

Saenger gives a rather elaborate description of these residua of gonorrhea, describing a macular vulvitis and sclerotic adenitis, urethritis, peri-urethritis, colpitis, endometritis, metro-endometritis, salpingitis, and in fact nearly all the inflammatory conditions which the gynecologist is required to treat. It is apparent that the gonorrheal origin of these lesions remains unproven, and that they exhibit no peculiarities necessarily inherent to gonorrheal infection. It is worthy of note that Saenger holds that the greater number of rectal strictures are of gonorrheal origin.

Bumm denies that gonococci lose their virulence, and holds that infection from an old case, if planted on healthy mucous-membrane, produces an acute attack; he states that the gonococci may persist and remain virulent in the genital tract for five or ten years. He still believes that the gonococcus is a pure mucous-membrane parasite, remaining in chronic cases quite superficial, and only exceptionally penetrating into other tissues and acting as the ordinary pyogenic micro-organisms do.

The prognosis of gonorrhea in women depends upon the frequency with which the endometrium and the tubes are affected. Of seventy-four cases observed from the beginning of infection to complete cure, Bumm states that sixty-nine had urethritis, fifty-three cervicitis, sixteen (twenty-three per cent.) endometritis, and seven (ten per cent.) salpingitis.

In tubal infection, he holds, treatment should be conservative. The patient should be put to bed at once, and should be given resorbent treatment. This is successful in the great majority of cases, although it often takes a long time. When the tube becomes converted into a large pus-sac with thin walls, operation is indicated—not, however, salpingotomy, but vaginal extripation of the uterus together with the inflamed tube.

This last contribution to the knowledge of gonorrhea, though bringing no new facts to the attention of the profession, is valuable as an authoritative statement, since Bumm and Neisser stand first in special knowledge of the gonococcus. These men accentuate the importance of bacteriological examination in all inflammatory conditions of the genitalia, and contradict a commonly accepted fallacy as to the comparative innocuousness of a long-standing gonorrhea; they state that the discharge of a neglected clap may remain contagious almost indefinitely, and bring before us with startling distinctness the danger of the disease when it attacks women.

It may be accepted without fear of contradiction, that Bumm's cases were treated in the most thorough and modern way known to science, and yet he tells us that ten per cent. suffered from salpingitis. He infers that in general statistics the percentage will probably be greater than this.

Perhaps the most valuable, if not the most important, teaching in the communications cited above, is the reliance which seems to be universally placed in the salts of silver.

## Reports on Therapeutic Progress

---

### THE SURGICAL TREATMENT OF FOCAL EPILEPSY.

SACHS and GERSTER contribute a paper on this important subject to the *American Journal of the Medical Sciences* for October, 1896. They draw the following conclusions:

1. Surgical interference is advisable in those cases of partial epilepsy in which not more than one, or at the utmost two, years have elapsed since the traumatic injury or the beginning of the disease which has given rise to the convulsive seizures.

2. In cases of depression or other injury of the skull, surgical interference is warranted even though a number of years have elapsed; but the prospect of recovery is brighter, the shorter the period of time since the injury.

3. Simple trephining may prove sufficient in a number of cases, and particularly in those in which there is an injury to the skull or in which a cystic condition is the main cause of the epilepsy.

4. Excision of cortical tissue is advisable if the epilepsy has lasted but a short time and if the symptoms point to a strictly circumscribed focus of disease.

5. Since such cortical lesions are often of

a microscopical character, excision should be practiced even if the tissue appears to be perfectly normal at the time of operation; but the greatest caution should be exercised in order to make sure that the proper area is removed.

6. Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy.

7. In cases of epilepsy of long standing, in which there is in all probability a widespread degeneration of the association fibres, every surgical procedure is useless.

#### COMPRESSION IN TRAUMATIC NEURITIS.

DELORME contributes an article (*Journal de Médecine*, June 25, 1896), accompanied by notes of ten cases, on the treatment of traumatic neuritis. The first case was that of a soldier who, having received a bullet wound in the neck, became a martyr to neuralgic pain for twenty-three years. The cicatrix was removed several times by operation, and the galvano-cautery, caustics, etc., were applied without success, for the burning, lancinating pain still continued. The least touch or draught caused agony. In the second case a soldier injured the last phalanx of the right index finger, and for several months complained of severe pain shooting up the rest of the hand and up the arm. The other cases were more or less similar, consisting of accidents due to kicks from horses, etc., to which soldiers are liable.

In all these cases the writer obtained surprising results by the following method of treatment: The exact extent of the painful area is defined; then the patient, either sitting or lying, is supported by assistants, and the operator compresses the affected part, such as the finger, between his own finger and thumb, with all his strength. This is done successively over the whole extent of the hyperesthetic area, over and around the cicatrix, beginning at the most painful point. If after the first application, which lasts only a few seconds, any hyperesthesia remains, the performance is repeated after a few minutes' rest, and this may even be done a second or third time after a few days' interval; in many cases a single sitting is enough. The pressed finger is then wrapped up for eight or ten days in a wool dressing. After this treatment the finger, which previously could not be touched, however lightly, without provok-

ing extreme pain, can be handled with impunity, the sensation of touch may show little or no alteration from normal, and in the course of a little time trophic disturbances, even of long standing, disappear. Thus, in the first case quoted by the author, the pain completely disappeared after two sittings, with a four days' interval; the hyperesthetic area had completely recovered; the shoulder, which before was kept in a drawn-up posture in the effort to obtain ease, returned to its normal position; and the general health of the patient underwent a veritable transformation. It is now three years since the pressure was applied, and there has been no return of the pain. The other cases are all more or less similar. The author, it may be remarked, does not employ a general anesthetic, as he rather fears production of syncope, and he even thinks that a local anesthetic, though possibly useful in some cases, might in some respects be inconvenient, as it is important to know exactly the limits of the painful area. Lastly, he remarks that it is necessary to eliminate any hysterical factor before having recourse to this somewhat heroic treatment. —*British Medical Journal*, Aug. 29, 1896.

#### THE TREATMENT OF HEADACHE BY THE ADMINISTRATION OF METHYL BLUE.

LEROY (*Berliner Klin. Woch.*, No. 45, 1896) concludes, from the study of a limited number of cases, that we possess in this drug a very active remedy in certain forms of disease, and that it is capable of not only relieving but permanently curing pain which has resisted all other methods of treatment.

The disorders which, according to his observation, are most amenable to the methyl-blue treatment, are habitual chronic neurotic headache and angiospastic migraine. The amount prescribed was one and one-half grains four times daily; in general, fifteen grains sufficed for a cure; in certain cases the treatment had to be repeated after a week's interval. Bladder irritation was prevented by using, as Ehrlich suggested, an equal amount of powdered nutmeg with each dose.

The drug was taken readily by the patients, with one exception, and the only objectionable feature was the dyeing of the urine a dark blue or green. In habitual headache—that is, of the pure nervous type, and not symptomatic of some other disease—the author says methyl blue is of exceptional

value, and that in the cases he observed it acted like a specific, not only relieving the pain, but curing the pathological condition.

In a case of angeiospastic migraine, four and one-half grains of the methyl blue, given in three doses, two hours apart, at the onset of the attack, prevented its oncoming. If the dose were not given until the height of the attack, the patient vomited it, and no benefit accrued. Given at the proper time it was always effectual, the pain remaining very slight, and disappearing entirely by midday. Besides this immediate effect, the methyl blue produced a further good result: the attacks have become less frequent, and now come on only once in three months.

The author also details a case of pyelonephritis in which the administration of methyl blue seemed to give remarkably good results; there was a large amount of pus in the urine, and the patient had passed a number of renal calculi, while a large tumor was present in the region of the right kidney. Heart lesion contra-indicated operation, and the treatment with methyl blue was tried. The urine was deeply colored, but no trace of color could be found in the pus-cells or their nuclei, nor were the numerous forms of bacteria colored. The renal colic was cured, and after the stoppage of the medicine the pus gradually continued to decrease and was only slight in amount. The tumor can no longer be felt. This may be a case of spontaneous cure, but the methyl blue may have had an effect also. The author would himself employ this form of treatment in another similar case. It is worthy of note that the methyl blue had no serious effect upon the weakened heart, and, if anything, seemingly benefited the cardiac condition.

The author would recommend the use of this drug in cases of angeiospastic migraine, in neurasthenia, and especially in cases of pure nervous headache; he, however, does not believe it should be used until all other known remedies have proved unavailing.

SCHINDLER (*ibid.*, No. 46, 1896) calls attention to the fact that the above paper of Leroy is not the first clinical observation upon this subject, and that he, together with GUTTMANN, made a far greater number of clinical observations upon this subject, which were published in 1892. They called especial attention to the remarkable results obtained in pure nervous headache and in migraine. The prompt action of methyl blue in these remote affections of the head is in accord with its action upon neurotic and rheumatic disease

in other portions of the body. In a *résumé* of the former article this author says: "Methyl blue is a good remedy, especially in headache of a purely nervous nature and in uncomplicated neuralgic and rheumatic pains of the lower extremities and trunk. A comparison with the other anti-neuralgics would seem to favor methyl blue. In drunkards and in neuroses which have as their basis pathologico-anatomical alterations, methyl blue has, of course, no action."

The author does not believe that Leroy's article loses in worth because it loses priority, but is rather of value in being a second observation confirmatory of the action of this drug.

The author has found the drug useful in treating ischiatic inflammations. A patient who had suffered for thirty years was relieved, and has had no relapse, after a dosage of seven and one-half grains daily for ten days. The drug may also be employed in relieving the pains accompanying pleuritis, bronchitis, and other affections of the lungs.

The author warns very strongly against an individual predisposition or idiosyncrasy on the part of some patients for this drug; and although, in the majority of cases, a daily dose of fifteen grains can be readily borne, there are cases where serious though not dangerous symptoms are produced. The mild symptoms are: weakness in the limbs, paresthesia, mental prepossession, giddiness, and desire to vomit. There is no fever, collapse, or change in nutrition, and no derangement of the stomach. Large doses produce more marked symptoms of irritation, but so far have given rise to none that were dangerous. The drug is harmless in small doses, and effectual, while it is not dangerous, in large doses.

#### A NOTE ON PICRIC ACID IN THE TREATMENT OF SUPERFICIAL BURNS AND SCALDS.

In the *British Medical Journal* of September 12, 1896, POWER gives his results in the treatment of burns by picric acid. As he states, the treatment of superficial burns and scalds has long seemed to be most unsatisfactory, for these injuries are attended with an unnecessary amount of inflammation, while the act of renewing the dressings is unduly painful. From time to time the writer has tried various methods of treatment, and he has come to the conclusion that the picric-acid treatment is by far the simplest and the most satisfactory. The method is well known in

France, where it has been extensively used by Professor Thiery, while Dr. Filleul and Dr. Papazoglou have done their best to disseminate a knowledge of its value.

The solution is made by dissolving a drachm and a half of picric acid in three ounces of alcohol, which is then diluted with two pints of distilled water, or, more accurately: Picric acid, 5 grammes; alcohol, 80 grammes; dissolve; add 1000 grammes distilled water. This is a saturated solution of picric acid.

The clothing over the injured part should be gently removed, and the burned or scalded portion cleaned as thoroughly as possible with a piece of absorbent cotton wool soaked in the lotion. Blisters should be pricked, and the serum allowed to escape, care being taken not to destroy the epithelial surfaces. Strips of sterilized gauze are then soaked in the solution of picric acid, and are so applied as to cover the whole of the injured surface. A thin layer of absorbent cotton wool is put over the gauze, and the dressing is kept in place by a light linen bandage. The moist dressing soon dries, and may be left in place for three or four days; it must then be changed, the gauze being thoroughly well moistened with the picric-acid solution, for it adheres very closely to the skin. The second dressing is left on for a week.

The advantages of this method of treatment are: first, that the picric acid seems to deaden the sense of pain; and secondly, that it limits the tendency to suppuration, for it coagulates the albuminous exudations, and healing takes place under a scab consisting of epithelial cells hardened by picric acid. A smooth and supple cicatrix remains, which is as much superior to the ordinary scar from a burn as our present surgical scar is superior to that obtained by our predecessors who allowed their wounds to granulate.

The writer has used this method for more than a year in hospital practice, both among out-patients and in-patients, and has every reason to be thoroughly satisfied with the results obtained. It is not an ideal method, for it stains the clothes and discolors the hands of the surgeon, but it is a great improvement upon anything else he knows of.

general practitioner. He does not attempt to discuss the nature, symptoms, and pathology of chronic endometritis, but confines himself to treatment.

There are two improvements in gynecology which make intra-uterine medication a much simpler thing, and one which can be much more freely and safely used, than was formerly the case. One is the principle of rapid dilatation of the cervix to any desired extent by graduated bougies, formulated by Hegar; the other is the regular and systematic use of antiseptics in all gynecological operative procedures, however simple. When the os was narrow, and its canal not patent—which, however, is rarely the case in old-standing endometritis really suitable for intra-uterine medication—we had formerly no means of reaching the endometrium except dilatation with sponge or laminaria tents—contrivances now entirely disused as being dangerous, clumsy, septic, and apt to lead to secondary mischief. Now we are able to reach any part of the uterine cavity in a short time, and, when rigid antiseptic precautions are used, with practical safety, but with this disadvantage—that anesthesia is required, and the manœuvre is, therefore, raised to the dignity of a considerable operation—at least, in the eyes of the patient.

Several methods of intra-uterine medication mentioned in Playfair's original paper, he now puts aside as absolutely inadmissible—such as injection of fluids, introduction of medicated tents, zinc points and the like, or of solid pieces of caustic, as recommended by Courty, experience having shown that such devices are either too dangerous for ordinary use, or too clumsy and ineffective; it would therefore be a waste of time to discuss them.

Perhaps, for general use, the plan of brushing over the endometrium with some medication is still one of the most generally applicable. The plan recommended in his original paper is as good as any other that has been suggested. Briefly, it consists in swabbing out the uterine cavity in the first instance with a flexible probe covered with a thin layer of cotton wool, dipped first in water and then in glycerin. The object of this is to wipe away the tenacious, glairy mucus which exists in such abundance in cases of chronic uterine catarrh. If the probe is bent in a suitable curve, there is generally no difficulty in introducing it through a cylindrical speculum, since the os and cervix are usually abnormally patulous. After this, a

#### ON MODERN METHODS OF INTRA-UTERINE MEDICATION.

PLAYFAIR in the London *Practitioner* for September, 1896, writes most interestingly upon a subject of great concern to every

similar probe is dipped in equal parts of absolute phenol and glycerin, and the uterine cavity is swabbed out with it. This application should be made twice in the week immediately following menstruation, and not repeated until after the next menstrual period. If practiced too near the expected commencement of menstruation it is apt to prove irritating, and he has then known it to cause a pretty sharp hemorrhage. Immediately after menstruation the deeper layers of the endometrium are doubtless more accessible, and thus a better result is obtained. He has never known any bad consequences follow this practice, probably because the strong carbolic is itself antiseptic.

There are, however, some drawbacks to this method of treatment: It is difficult to use if the cervical canal is not patulous, and if the practitioner is rough and unaccustomed to gynecological manipulations it may cause a good deal of pain; moreover, it takes considerable time and repeated applications to be of permanent benefit. The author has usually limited it to two sittings within the week following the period, and he is inclined to say that from six months to a year would be required to produce as good a result as can now be obtained from one-fourth the number of "treatments," and these limited to six weeks, by one of the improved methods presently to be discussed. At the same time it is right to point out that it requires no expensive and elaborate plant to carry out; that it involves no anesthesia or preliminary dilatation; and that, although tedious and slow, in well selected cases it is thoroughly effective. He believes in the use of equal parts of crystalline carbolic acid and glycerin as a topical application. Iodized phenol, however, and other reagents have been used with advantage.

Curettement is unquestionably at present the favorite and fashionable method of intra-uterine medication. It consists in scraping away the superficial layer of the endometrium, and generally after this has been done the surface thus bared is swabbed with liquor iodi or some similar application, used as an antiseptic, but which may, so far as a single application can, have some modifying influence on the endometrium. If this plan is not adopted, or in combination with it, packing of the uterine cavity with antiseptic gauze is frequently practiced.

Curettage was at first chiefly used for cases of the so-called "fungoid endometritis"—that is, cases in which numerous vegetations are

scattered over the endometrium, giving rise to profuse menorrhagia. No one who has used it for cases of this kind can doubt its efficacy. Every gynecologist must have met with cases of menorrhagia which have been completely and permanently benefited or cured by curettement. Of late, however, it has been maintained by many that it is equally effectual in chronic uterine leucorrhea of old standing, uncomplicated with menorrhagia, and in which there is no reason to suppose that vegetations of the endometrium exist.

It is claimed that one thorough curettement will do as much as a more extended treatment of other kinds, and that it may itself be curative. If this were so, no doubt the gain would be great. This, however, is certainly not the writer's experience. He has seen many cases of very marked chronic endometritis which had been curetted—sometimes more than once—and which were very little bettered by this operation. He has curetted cases of this kind with a like unsatisfactory result. When one reflects that, in curetting, only the superficial surface of the endometrium is scraped away, and that the deeper portions of the uterine glands, the parts principally affected, are left untouched and their nutrition unmodified by such medication as is given by carbolic acid or by the electric current repeated at intervals, the merely temporary good result following curetting is readily understood. As a preliminary, however, to other treatment, or in cases in which treatment extended over weeks or months is impossible, curetting of the endometrium will always be an important and valuable resource, even when there is no evidence at all of the existence of vegetations.

Playfair prefers, as a means of intra-uterine medication, the application of the negative electric current after the plan introduced by Apostoli. He makes this statement with fear and trembling, for the mere mention of Apostoli and his methods acts on some gynecologists as a red flag on a bull. No words are too strong to express their contempt for a remedial agent which has certainly been discredited by the over-zealous advocacy of its originator and by the prejudice of its opponents. It must be admitted at once that as regards fibromyomata the use of electricity has not by any means justified the expectations, far too high-pitched as they were, at one time formed with regard to it. This is not the place to discuss that subject; but,

briefly, this is due to the fact that, in small hemorrhagic fibroids, electricity, although its hemostatic power seems to be proved to demonstration, is too uncertain in its action to be reliable, its effects being negated by physical causes varying in each particular case and needless to discuss here, and that therefore radical treatment by removal of the appendages is generally better, while in large tumors it is usually inapplicable. The use of the current to promote absorption has been discontinued by common consent as too dangerous for general use. But the application of the negative current to the endometrium in non-myomatous uteri, for endometritis and severe dysmenorrhea, is on altogether a different footing. The precise method of its action is doubtful, but it appears to modify the nutrition of the endometrium and its deep-seated glands in a very remarkable manner.

The author has rarely used more than five or six applications—generally three after one period and two after another—of from 80 to 100 milliampères of the negative current. This is practically painless, nor has he seen a single case in which any subsequent mischief resulted. The efficiency of this method of intra-uterine medication is best proved by the frequency with which it is followed by pregnancy in old-standing cases of acquired sterility. It will generally be admitted that there is no better test than this of a healthy endometrium when the pregnancy has been preceded by a long period of sterility.

Take, for example, such a case as the following, which is selected almost at random:

Mrs. L., who had never been pregnant, suffered from very profuse uterine catarrh and severe dysmenorrhea, for which she had the cervix dilated and the endometrium curetted by a well known gynecologist, with no great benefit. Playfair treated this patient with the electro-negative current in October and November, 1892, making five applications. The discharge was stopped and her general health greatly bettered. She missed her period in January, 1893, and was delivered of a healthy child in November of the same year.

It would be difficult to doubt the relation of cause and effect here, and it is to be noted that this patient had already been treated by curettement.

The author is, therefore, decidedly of the opinion that for neatness and efficiency the electrical treatment of the endometrium is clearly the best at our disposal in suitable cases.

# THE REMOVAL OF FOREIGN BODIES FROM THE SUPERFICIAL TISSUES OF THE EYE, AND THE TREATMENT OF THE RESULTING LESIONS.

In the *Occidental Medical Times* for August, 1896, BRIGGS states that every eye in which symptoms of irritation, congestion, photophobia, lacrymation, etc., are present, should be examined with scrupulous care for foreign bodies.

In all eye-injuries the rules of antiseptic surgery should be carefully observed. Never attempt to remove a foreign body from the eye with an instrument that is not aseptic.

Cleanse the eye with a 1:5000 bichloride solution, and apply antiseptic dressings, when there is the least suspicion that the wound may be infected.

When suppuration of the corneal wound has taken place, active measures must be promptly applied to check the trouble. In beginning of trouble antiseptic dressings, iodoform, hot water, may be tried, but the galvano-cautery or subconjunctival injections of bichloride solution should be used if improvement is not prompt.

Use the greatest possible care in removing foreign bodies from the cornea, to avoid injury to healthy tissue. Carefully insert a spud with a dull edge under the foreign body, and lift it out instead of scraping over the body, as is too often done.

When the foreign body is iron or steel, the electro-magnet is occasionally valuable. When the steel has nearly passed through the cornea this is the safest means of extracting it. The entrance wound must generally be enlarged to enable the magnet point to come in direct contact with the metallic fragment.

Dirt, lime, powder, etc., can generally be removed by directing a stream of warm boiled water against the open eye, assisting the process by gently wiping the foreign substance away with a pledget of absorbent cotton. Caustic substances must be removed with the greatest possible haste.

Powder, which cannot be washed away, should be carefully removed by a sharp-pointed knife or needle. Do not dig too energetically, especially near the central portion of the cornea, as much greater injury is frequently caused by too persistent and unskilled efforts at removal of powder grains.

Powder grains in the conjunctiva are readily removed by snipping off a small piece of

conjunctiva with scissors. They rarely cause irritation, but are cosmetically objectionable.

After removal of caustics, molten iron, and substances which cause extensive injury to the cornea and conjunctiva, great care must be taken to prevent the lids adhering to the eyeball. The transplantation of rabbits' conjunctiva, or Thiersch's method of skin-grafting, may be necessary to prevent this unfortunate condition taking place.

#### *CHELIDONIUM IN THE TREATMENT OF CANCER.*

Among the many medicinal virtues that have been popularly imputed to the juice of *Chelidonium majus* is that of curing warts. Acting on this hint from domestic practice, Dr. DENISSENKO (*Vratch*, 1896, No. 30; *Deutsche Medizinisch-Zeitung*, Sept. 24, 1896) has tested its action on carcinomatous growths in the municipal hospital at Brjansk. In his early experiments he used the fresh juice of the herb, but those trials were imperfect, partly because the fresh juice could be obtained only during two months in the year. Consequently, since February, 1895, he has been using the extract found in the shops.

His method of employing chelidonium is as follows: He directs that from twenty-two to seventy-five grains of the extract shall be taken internally, dissolved in distilled water or peppermint-water, every day throughout the treatment. Into the substance of the tumor, as close as possible to the boundary between it and the healthy tissue, he throws a number of injections of from two to four drops of a mixture of equal weights of the extract, glycerin, and distilled water, not exceeding a syringe-ful in all. The frequency with which these injections are given is not stated. If the tumor is ulcerated, he paints its surface twice a day with a mixture of one or two parts of the extract and one part of glycerin. Iron, quinine, and other supporting remedies are employed according to the indications.

Except in a few cases, the internal use of the drug caused no disturbance of the stomach, but the painting of the ulcerated surface gave rise to a slight transitory burning. It was different with the parenchymatous injections; in all instances, after the injections, especially after the first one, there was burning pain at the site of the operation, the patient felt weak, experienced a more or less severe chill, and then the temperature rose to between 100° and 102°. Although

these symptoms disappeared on the following day, Dr. Denissenko saw reason to exercise a certain amount of caution in the use of the injections.

The effects of this treatment were shown in the course of a very few days. They were the following: 1. The sallow hue of the skin disappeared. 2. Softening of the tumor set in. 3. After from three to five days, there formed at the points of injection fistulous tracts about which the softening process went on with special rapidity. 4. In from fifteen to twenty days a line of demarcation could be distinguished between the morbid and the healthy tissues; the one seemed to be forced away from the other. In general the tumor diminished more than half in circumference, and the affected lymphatic glands of the neighborhood underwent involution.—Editorial in *New York Medical Journal*, Oct. 10, 1896.

#### *THE THERAPEUTIC VALUE OF HYDROBROMATE OF SCOPOLAMINE IN PLASTIC IRITIS.*

In the *American Journal of the Medical Sciences* for November, 1896, OLIVER concludes an article on this subject as follows:

Hydrobromate of scopolamine is of the greatest value in the local treatment of the various forms of plastic iritis. Its primary reparative action and quieting power, as compared with those of similar doses of sulphate of atropine, in the treatment of plastic iritis, are generally much more prompt, even when the latter drug is used in doses equal to quadruple or quintuple the strength of the former. Its healing and soothing effects do not seem to be so lasting, even when the drug is used in four or five times the strength of the atropine.

For quick and active measures, which are so eminently necessary in incipient cases of plastic iritis, and during the early stages of inflammatory reaction, the scopolamine salt is to be preferred to the atropine; but where prolonged use of such drugs is necessary, as in many cases of the chronic form of the disease with subacute exacerbations, the alternate employment of scopolamine and atropine seems empirically to be the best method of local administration that has been devised.

As clinically employed, the best salt of the alkaloid seems to be the hydrobromate; the best method of instillation, dropping the solution upon the upper corneal border while the lower punctum is everted and the cor-

responding canaliculus is pressed upon; and the most efficient amount to be used at one sitting, two drops of a one-tenth of one per cent. strength (1:500), repeated, if necessary, as often as three times during the course of an hour, and preceded, when desired, as in some instances where there are much irritation and pain, by two drops of a two-per-cent. solution of hydrobromate of cocaine a few minutes before each instillation of the scopolamine.

#### *CLIMATE IN THE TREATMENT OF DISEASE.*

The joint article by Dr. HERMANN WEBER and Dr. MICHAEL FOSTER upon "Climate in the Treatment of Disease," which appears in the first volume of Dr. Clifford Allbutt's System of Medicine, is a very careful piece of work, and gives probably the best summary of the subject at present available. We propose to indicate some of the principal views of the writers which serve to "mark time" in this department of practice—a department beset with great and peculiar difficulties. Exact knowledge and definite therapeutic rules are more difficult of attainment in climatology than in most other branches of medicine, owing to the complexity of the phenomena involved, the vast range of the facts which must be passed in review, and the comparatively recent growth of systematic attention to the subject. But the importance of the subject is great and growing. The writers of the article in question remark very justly that "in former times climatic treatment was almost limited to diseases of the respiratory organs, but at present we know that the treatment of almost every chronic deviation from health may be assisted by judicious change of climate." What is required is more precision in the choice of localities and a juster appreciation alike of the potentialities and the limits of climatic therapeutics. The patient who expects that change of climate is all that is required to cure his malady, and the practitioner who recommends a given climate in a haphazard way and on mere general principles, represent two opposite types of error on this subject which a wider and juster knowledge will serve to dissipate.

Naturally the case of phthisis first presents itself for consideration, owing to its pre-eminent importance and to the fact that it has received more study and attention than that of other diseases. The selection of a

suitable climate for a phthisical patient is, as the writer truly says, "often one of the most difficult problems with which the physician is confronted." This arises not so much from the obscurity of the subject as from the fact that our choice of climate is so often circumscribed by extraneous considerations, such as the poverty of the patient, the necessity of selecting a locality where facilities exist for earning a livelihood, and the difficulties of securing suitable accommodation, congenial surroundings, and proper companionship. A locality theoretically desirable on meteorological grounds may be too inaccessible, or the hotel accommodation may be inferior, or there may be a complete lack of civilized society, occupation, and amusement; we cannot afford to neglect any of these considerations, but it is obvious that they serve to complicate the subject to an indefinite extent. In any case of phthisis calling for climatic change we should first consider whether the high altitudes are likely to be suitable. Drs. Weber and Foster are of opinion that "early cases of either unilateral or bilateral phthisis in young and fairly vigorous persons, in which the disease is of a limited character and the pyrexia moderate, should be sent to the Swiss Alps in preference to any other resort. In young persons a sojourn of one or two years in the Alps will probably not only arrest the disease, but so establish the constitution that the patient may cautiously resume his occupation at home." We believe this to be a sound rule, though we should be disposed to express the prognosis in such cases a little more guardedly. Disappointments are frequent, but the general results are undoubtedly good and often surprising. We are entirely in accord with the writers with regard to the succeeding paragraph: "In the early days of high-altitude treatment a history of hemoptysis was looked upon as a bar to the employment of the climate; the reasons for this belief were mainly theoretical, and a more extended experience has shown that the very reverse is the fact and that hemorrhagic cases do particularly well there." The confusion which has existed in the profession with regard to this subject is regrettable. There are still some who teach that hemoptysis is a bar to the sea voyage, just as it was formerly regarded as a bar to the mountains, the one opinion being as unfounded as the other. The true view seems to be that existing or very recent hemorrhage precludes change of climate altogether, but that past

hemorrhage is no bar to the sea voyage or the mountains: it may even, in a guarded and limited way, be held to be an indication for the mountains, but the problem will generally be better decided on other grounds. The writers also recommend the mountains in limited and quiescent cases of the third stage of phthisis, and in cases that have arisen out of, or are complicated by, pleurisy. The chief contra-indications to the mountains are held to be albuminuria, degenerative disease of blood-vessels, ulceration of the intestines, advanced laryngeal mischief, especially perichondritis and ulceration of the arytenoids, active tuberculization, extensive destruction of lung tissue, constitutional erethism, and advanced age. These, we believe, are thoroughly sound rules. Colorado is recommended as possessing a climate "little, if at all, inferior to that of the Swiss Alps," and affording ample opportunities for the earning of a livelihood. "Young subjects, the children of tubercular parents, not themselves tubercular, but for whom a change of climate is thought advisable as a prophylactic measure—as, for instance, after a pleural effusion—will do better in Colorado than elsewhere." Australia is recommended in cases of early consolidation in which there is no fever and in quiescent cases where excavation has ceased to progress. Similar rules hold with regard to South Africa, but it must not be forgotten that in that country nearly all the favorite resorts are at a considerable elevation (from 2000 to 4000 feet), whereas most of the Australian plains (the Darling Downs are an exception) are at a low elevation. We have little doubt that when the accommodation is improved South Africa will hold a leading place as a sanatorium. At present only the harder type of patient should be sent thither. The cases suitable for Egypt are thus enumerated: (*a*) cases complicated by bronchitis in which emphysema is also present; (*b*) cases of bronchiectatic phthisis which have already spent a winter or two in the Alps; (*c*) cases for which the Riviera is too cold; (*d*) cases of early consolidation in which for some reason the Alps are contra-indicated; (*e*) cases with albuminuria in which the destruction of lungs is not very great; and (*f*) cases in which insomnia and nervous irritability form prominent symptoms. The leading contra-indications to Egypt are intestinal ulceration or a tendency to diarrhea, laryngeal ulceration, and the early occurrence of acute pneumonic symptoms. The Riviera is recommended for

cases which find the Alps too cold, for cases complicated with catarrhal pneumonia or bronchitis, and some forms of laryngitis. Madeira may be tried where there is much irritability of mucous membranes or emphysema. The sea voyage is useful (*a*) where phthisis is part of a general breakdown from overwork; (*b*) in cases of limited consolidation, without fever; and (*c*) in some cases where cavity formation is not extending. The contra-indications to the sea are laryngeal and intestinal complications, debility and fever. We forbear criticising the above rules for want of space, but at least in the main we can fully endorse them.

We now turn to the cases of other diseases, for which the rules are easier and less complicated. Bronchitis in young persons is often benefited by the mountains, but in elderly persons the Riviera, Egypt or the Canaries will be found more suitable. Where there is irritable cough without expectoration, Madeira, Pau, Arcachon, Torquay or Queens-town may be tried. Emphysema calls for dry and warm inland or coast climates, or if attended by dry cough the resorts just enumerated for bronchitis will be found suitable. Asthma is too erratic a disease to admit of definite rules: young subjects are often benefited by a stay in the Alps; senile patients may try Egypt or the Riviera; many asthmatics do best in large towns. "Scrofula"—*i. e.*, lymphatic tuberculosis—is notably benefited by a bracing marine resort, and sea voyages are also useful. Gout and rheumatism demand warm and dry inland climates or fairly warm seashores. Warm and dry climates are useful also in renal and vesical diseases. Dyspepsia is often signally benefited by change of climate, but precise rules are difficult to formulate. Dry, elevated regions and warm, bland climates will be found suitable in different cases. Nervous affections will often be influenced favorably by climate, change, and travel. We must demur to the recommendation which Dr. Weber and Dr. Foster make of sea voyage in hypochondriasis, at all events in its graver forms. On the whole, when there is either much excitement or much depression, sea voyages are contra-indicated. The mountains are also, on the whole, unsuitable for most cases of nervous disorder. Sedative localities, like Pau, or moderately bracing localities, like Malvern or Bagatz, will suit different cases.

We conclude with the paragraph in which Drs. Weber and Foster sum up the characteristics of the climate of England. "We

must acknowledge that the climates of England are rather moist, that the air is often dull and sunless, that rain falls on comparatively many days and is distributed over many hours, that the wind is often high and chilling, and that the shelter is limited. On the other hand, the hygienic conditions are better than anywhere else, the food is good, and the separation from the family is less. The climates of England belong to the most health-giving climates for the fairly vigorous, but are less good for the delicate invalid. If, however, a delicate person is obliged to stay at home or near home, it is often possible for him by judicious management to obtain great benefit by availing himself of all the advantages and defending himself from the injurious influences of the home climate."—Editorial, *Lancet* (London), Aug. 8, 1896.

#### A WORD ON THE SYMPTOMS AND TREATMENT OF PLEURISY.

In the *Northwestern Lancet* of October 1, 1896, ABBOTT, in discussing the subject of pleurisy and its treatment, says that the salicylates and other anti-rheumatics have been recommended on the theory that pleurisy is rheumatic. While some cases may be rheumatic, others certainly are not, at least one-third being tubercular; and in the writer's experience this class of remedies has failed in a great number of cases to accomplish anything in the way of amelioration or cure, doing no good in promoting the absorption of fluid, and little if any in relieving the other symptoms. Fixation of the chest by plasters in some cases seems to afford relief by preventing motion and the painful rub of inflamed surfaces, but in many patients the irritation caused by the plaster is more complained of than the pleuritic pain, while the presence of the plaster interferes with accurate examination of the patient.

Blisters make a bad matter worse. It is bad enough to suffer the ills that Providence sends, without being tortured by the doctor in addition. As to poultices, they are a delusion and a snare: even if hot when applied, they soon become cold, and the alternation of the hot, slimy nastiness with the cold one cannot do much good, while the interval between the removal of one and the application of the other is fraught with danger to the patient, who is uncovered for the purpose of changing. The same objection applies to the use of poultices in pneumonia. We often hear of wonderful results from these things,

but they are more often *post hoc* than *propter hoc*.

If any external application is used, none is so good as cold. An ice-coil or an ice-bag would often alleviate pain and give great relief. Cold cloths are bad because they make the clothing wet.

Morphine or some form of opiate, of course, will do better than anything for the relief of pain, and should be used freely enough to make the patient comfortable. If an effusion comes on rapidly enough to cause dyspnea, stimulants may be needed; and medication should be adapted to symptoms and conditions which demand it.

If an effusion is large, no time should be lost in removing it. The physical signs are sufficient to satisfy us in most cases in regard to this; but, if not, a needle thrust into the cavity will soon settle the diagnosis. In nearly all cases where there is an effusion there is a thick plastic exudation on the surface of the pleura. If we wait for the lung to become compressed and the exudate to become organized, we will have a hopelessly crippled lung. The argument has been advanced that if we aspirate early the inflamed surface will immediately pour out a fresh supply, and so no good will be accomplished. But even if this does occur, we can aspirate again; it will not take a great amount of food and drink to furnish a fresh supply of serum. We see too many sunken chests that are the results of too long waiting, not to feel convinced that an early interference is the wisest course to pursue. It is not necessary to remove all the fluid—indeed, the removal of a moderately small amount will often relieve the pressure and start the process of absorption, which will then go on unaided. As soon as the patient begins to cough or to feel a sense of tightness around the chest, it is time to stop. If the physical signs are sufficient to convince us that fluid is present, one negative puncture should not discourage us; the needle may have simply penetrated an adhesion on one of the numerous trabeculæ present, and then of course no fluid would be obtained. If the needle and skin and doctor are clean, there is no danger in making enough punctures to give absolute certainty.

Absorbents, as iodides, etc., are of little avail, though they amuse the patient while we are waiting to see what nature will do. Cathartics and diuretics will accomplish much if liquids are kept from the patient; otherwise they will not do much good. The writer

has seen large effusions rapidly absorbed in this manner, which as rapidly reappeared when the free use of water was allowed, to again disappear on placing the patient again on the dry diet. This combination of drugs and diet will do more than any form of medication; but if the effusion persists or the dyspnea is urgent, nothing is to be gained by waiting, while much may be lost. It is well, if the case be not urgent, to wait and see what nature will accomplish, but we should not confound natural recuperation with the strain of natural endurance, which is liable at any moment to result in collapse. We do not carry out this policy in other cases. In obstetrics we do not wait so long before we use version or the forceps; in dentistry we pull or fill the offending tooth; in abdominal work we perform laparotomy, even for exploration; but in thoracic effusion too many will sit down, after demonstrating the presence of a painful of water, and wait, like Mr. Micawber, for something to turn up. If the aspirator shows pus instead of serum, the question arises: Should we make a free incision, or wait? The decision then depends much on the condition of the patient and the character of the pus. If the pus is septic and the temperature high, the sooner the whole cavity is emptied and drained, the better; if not, there is no harm in waiting a moderate time to see if the pus again forms.

Years ago we used to hear a great deal about serous effusions becoming purulent after repeated aspirations, and the supposition was advanced that all or most effusions were serous in the beginning; but since the days of assepsis we hear very little of changes of that sort.

#### WALCHER'S POSITION IN PARTURITION.

M. E. FOTHERGILL, of Edinburgh, in the *British Medical Journal* of October 31, 1896, says that Walcher's position—the *Walchersche Hängelage*—was first described by Walcher in 1889 in a short article in the *Centralblatt für Gynäcologie*. By placing the parturient patient in the lithotomy posture, and then allowing the legs to hang freely down so that the feet do not touch the floor, the true conjugate is increased about one centimeter; this statement has been proved by numerous observers abroad, and the posture is now in use as a matter of routine in several German hospitals. It is employed in all high forceps operations, in extractions after turning, and after perforation of the head. Fothergill has

found the posture extremely useful in several cases, which are briefly noted.

In posing the patient, all that is necessary is to see that the buttocks are quite at the edge of the bed or table used, and high enough to allow of the feet hanging clear of the floor; pillows may be placed under the buttocks if the bed is low. There is a tendency to pull the patient off the bed; but she may be held by the anesthetist, or bands may be passed under her arms and fastened to the bed or table-legs so as to hold her in position. In this posture the axis of the pelvic brim presents downwards at an angle of about 40 degrees; therefore, in order to exert traction in the proper direction with forceps, the operator must sit on a low stool, or on a cushion placed on the floor.

In high forceps cases, and after perforation, the position saves (1) the strength of the operator; (2) pressure on the head; (3) pressure on the symphysis; (4) pressure on the perineum by forceps. In cases of difficulty at the brim not needing forceps, and in breech cases, the position saves (1) exertion to the uterus and abdominal muscles; (2) pressure on the head; (3) pressure on the pubic symphysis. In all cases, with or without forceps, where the perineum is in danger, extension of the legs at the hips is of advantage in relaxing the integument and subjacent structures at the vulvar orifice.

#### THE MANAGEMENT OF THE SENILE HEART.

BELL writes on this important subject in the *Northwestern Lancet* of October 1, 1896. It is a topic which, though well worn, is always of interest, and therefore we present our readers with his views. He thinks that for the relief of the more or less high intra-arterial pressure we are to rely largely on the iodides and nitrites. He has found the iodide of sodium, in from two- to five-grain doses, repeated three times daily, of marked benefit in dilating the arterioles, thus reducing intra-arterial pressure; the iodides, having a much more prolonged action than the nitrites, are to be preferred for internal administration. The digitalis group, consisting of digitalin, strophanthus, strychnine, caffeine, sparteine, etc., render most excellent service in giving tone to the weakened myocardium, when combined with vascular stimulants like the iodides and nitrites.

In the management of pronounced cardiac insufficiency, no method of treatment has

proved so eminently satisfactory in the writer's hands as that of subcutaneous medication, assisted by baths, saline cathartics, Swedish movements, and massage. During the past three years it has been his pleasure to see many cases of advanced cardiac dilatation respond to strychnine, digitalis, nitroglycerin, and atropine, hypodermically administered, which would speedily have succumbed under any other treatment at his command.

In order to secure the best possible results, strychnine, digitalin and nitroglycerin should be combined for a time, later omitting the digitalin, or using it interruptedly, according to indications, in every case increasing the dose of strychnine until it produces muscular twitching, and there maintaining it. The smallest dose of nitroglycerin capable of producing the desired dilatation of arterioles should be the rule. It has been the writer's custom to begin with one-fortieth of a grain of strychnine, repeated every six or eight hours, gradually increasing the dose until its characteristic muscular manifestations appear, always combining it with nitroglycerin, and adding digitalin as indicated.

Subcutaneous medication is especially indicated in the aged, owing to their naturally feeble gastric absorption, but more especially in the management of cardiac dilatation owing to the accompanying gastric catarrh resulting from venous engorgement. It is urged against the subcutaneous method of treatment that it requires the presence and expense of a trained nurse; on the contrary, any intelligent person can be quickly trained to use the hypodermic syringe, thus enabling the physician to carry out the treatment at the patient's house without additional expense.

In suitable cases, saline baths of a proper temperature are an efficient aid in freeing the peripheral circulation, thus relieving venous engorgement and its attendant ills. Bell begins with a bath of ten minutes' duration—forty gallons of water at 100° F., gradually lowered to 92°, holding in solution four and one-half pounds of chloride of sodium. This is repeated daily for some days, then less frequently, gradually increasing the amount of salt, as well as the duration of the bath, from day to day, until the patient remains in the bath at least twenty minutes. He has never observed any unpleasant effects; on the contrary, in the majority of cases patients have expressed themselves as feeling relieved and refreshed. During the bath the pulse becomes slower and fuller, respiration slower

and deeper, the cardiac impulse stronger and more circumscribed, and apparently, at least, temporary decrease in the transverse cardiac dullness.

Massage and Swedish movements properly applied are useful aids in improving the circulation, the latter in the form of movements of resistance being of especial advantage owing to the feeble muscular movements and sedentary habits of senile patients.

Saline cathartics cautiously employed are especially useful in relieving the more or less constant gouty condition present after middle life; later they prove invaluable in removing dropsical accumulations.

*THE VALUE OF ANTI-STREPTOCOCCIC  
SERUM IN THE TREATMENT OF  
SEVERE PUERPERAL SEP-  
TICEMIA.*

J. I. WILLIAMS writes in the *British Medical Journal* of October 3, 1896, in regard to this most interesting therapeutic question. He has had six cases of his own in which he has used the serum, and has collected eight from literature. Of these fourteen cases of severe puerperal septicemia treated by anti-streptococcic serum, two ended fatally; eight were primiparous women varying in age from twenty-two to thirty years; one was a case of abortion, and one a multiparous woman with a rickety pelvis. In Vinay's cases (included in this list) no information is given as to age, character of labor, or number of pregnancies. Excluding these, we have left ten in which there is a definite record of the patient's state before and after the use of the serum. The labor was instrumental in six cases, lingering in one, and normal in two. In all, the placenta came away easily and completely. Information as to the integrity of the perineum is furnished in seven cases; it was torn but not sutured in four, torn and sutured in two, and uninjured in one. The sutured perineum in Case V healed by first intention, but in Gaulard's case it was curetted and resutured. In six cases the lochia were scanty, and in two suppressed. The reaction of the vaginal discharge was ascertained in three cases: once it was found acid, and twice alkaline. The writer's investigations into the reaction of the vaginal discharges in cases of puerperal septicemia during the past years seem to indicate that alkaline reaction most frequently accompanies septic intoxication—sapremia; and acid reaction, septic infection—septicemia. With

the former reaction the lochia were usually found free and fetid, and with the latter scanty or suppressed. In the ten cases referred to, symptoms of the disease set in from within a few hours of labor to the eighth day. The use of constitutional agents combined with local and instrumental treatment was tried in all the cases before the serum injections were resorted to, for a period varying from two to fifteen days. The earliest day after labor on which the serum was used was the fifth day, and the latest the nineteenth.

The serum was not injected in a single case without a previous thorough trial of the usual constitutional and local remedies. The state of the pelvic organs was ascertained in nine cases, and with two exceptions, where there was uterine tenderness, they were found to be normal. The cases were characterized by severe febrile symptoms, and in some there was diarrhea and vomiting. It must, of course, be admitted that puerperal infection may be independent of streptococci, but the conjunction of certain symptoms, rigors, high fever, and a rapid breaking up of the general condition, permit us to affirm the probability of infection due to streptococci. Certainty is only to be obtained by a bacteriological examination, such as was made in two cases, and proved beyond doubt that these two were cases of true streptococcic infection—puerperal streptomycolysis.

As to the general effect of the serum, Williams states that following each injection the previously hot, dry and inactive skin passed into a state of moisture and active perspiration; the parched lips and dry tongue became moistened; suppressed lochia and lactation reappeared; delirium, insomnia and restlessness passed off into a refreshing sleep, from which the patient awoke feeling better in body and clearer in mind. Headache and mental torpor were usually dispelled, but exceptionally the headache remained for hours, the patient otherwise feeling much relieved. The headache, which was described as "peculiar," was sometimes frontal and sometimes occipital.

In three cases no benefit resulted from the injections.

Vinay believes the injections to be more effective and more immediate in their action when they are made early and at the time of the evening when there is a spontaneous rise in the temperature. Local treatment, curettage, and antiseptic washings are not to be neglected.

In every case except three, the degree of temperature and the frequency of the pulse were reduced after each dose of serum—in from six to twenty-four hours. The temperature in Case I fell from  $104^{\circ}$  to  $102^{\circ}$  in six hours after ten cubic centimeters of the serum (Pasteur Institute) had been administered, but it rose to  $103^{\circ}$  eighteen hours later. A second dose, of twenty cubic centimeters, reduced it to normal in ten hours, and it remained so. In Case III the temperature followed an exceptional course: after a single dose of thirty-five cubic centimeters (Ruffer's serum) it fell from  $104.4^{\circ}$  to  $104^{\circ}$  in six hours; at the twelfth hour (midnight) it rose to  $105^{\circ}$ , but at the eighteenth hour it fell to  $102^{\circ}$ , and at the twenty-fourth hour to  $99.2^{\circ}$ , and remained under  $100^{\circ}$  from this time onwards. This was the only instance in which a rise was observed after an injection. In three cases the temperature fell to normal in twenty-four hours. The pulse-rate varied with the temperature.

Two of the cases proved fatal. The first received a daily injection of twenty cubic centimeters (British Institute) for three consecutive days, with no observed benefit; the patient died on the fourteenth day, the fever remaining high to the last. With regard to this case, it was probably one of streptococcus infection, and had a larger initial dose been administered a different result might perhaps have been obtained; but if it was a case of staphylococcus infection, of course no benefit could be expected. This shows the supreme importance of a bacteriological diagnosis. The latter case, however, stands in a different light. Here a bacteriological examination had been made, and the case undoubtedly was a true example of streptococcus infection—streptomycolysis. A dose of ten cubic centimeters of serum (Marmorek) was injected on the fourth, fifth, sixth, and seventh day after confinement, and by it the temperature was reduced to normal on the ninth day. On the evening of this day, however, the patient was seized with bilious vomiting and meteorism. The next day she was much worse, developed uncontrollable vomiting and became semi-comatose, and died on the eleventh day, the temperature remaining low to the end. The serum was effective in reducing the temperature, yet the patient died two days later during convalescence. Gaulard, after the post-mortem examination, attributed her death to the use of too much serum. The total amount injected was forty cubic centimeters (Marmorek), spread over

proved so eminently satisfactory in the writer's hands as that of subcutaneous medication, assisted by baths, saline cathartics, Swedish movements, and massage. During the past three years it has been his pleasure to see many cases of advanced cardiac dilatation respond to strychnine, digitalis, nitroglycerin, and atropine, hypodermically administered, which would speedily have succumbed under any other treatment at his command.

In order to secure the best possible results, strychnine, digitalin and nitroglycerin should be combined for a time, later omitting the digitalin, or using it interruptedly, according to indications, in every case increasing the dose of strychnine until it produces muscular twitching, and there maintaining it. Information as to the integrity of the perineum is furnished in seven cases; it was torn but not sutured in four, torn and sutured in two, and uninjured in one. The sutured perineum in Case V healed by first intention, but in Gaulard's case it was curetted and resutured. In six cases the lochia were scanty, and in two suppressed. The reaction of the vaginal discharge was ascertained in three cases: once it was found acid, and twice alkaline. The writer's investigations into the reaction of the vaginal discharges in cases of puerperal septicemia during the past years seem to indicate that alkaline reaction most frequently accompanies septic intoxication—sapremia; and acid reaction, septic infection—septicemia. With

the former reaction the lochia were usually found free and fetid, and with the latter scanty or suppressed. In the ten cases referred to, symptoms of the disease set in from within a few hours of labor to the eighth day. The use of constitutional agents combined with local and instrumental treatment was tried in all the cases before the serum injections were resorted to, for a period varying from two to fifteen days. The earliest day after labor on which the serum was used was the fifth day, and the latest the nineteenth.

The serum was not injected in a single case without a previous thorough trial of the usual constitutional and local remedies. The state of the pelvic organs was ascertained in nine cases, and with two exceptions, where there was uterine tenderness, they were found to be normal. The cases were characterized by severe febrile symptoms, and in some there was diarrhea and vomiting. It must, of course, be admitted that puerperal infection may be independent of streptococci, but the conjunction of certain symptoms, rigors, high fever, and a rapid breaking up of the general condition, permit us to affirm the probability of infection due to streptococci. Certainty is only to be obtained by a bacteriological examination, such as was made in two cases, and proved beyond doubt that these two were cases of true streptococcic infection—puerperal streptomycolosis.

As to the general effect of the serum, Williams states that following each injection the previously hot, dry and inactive skin passed into a state of moisture and active perspiration; the parched lips and dry tongue became moistened; suppressed lochia and lactation reappeared; delirium, insomnia and restlessness passed off into a refreshing sleep, from which the patient awoke feeling better in body and clearer in mind. Headache and mental torpor were usually dispelled, but exceptionally the headache remained for hours, the patient otherwise feeling much relieved. The headache, which was described as "peculiar," was sometimes frontal and sometimes occipital.

In three cases no benefit resulted from the injections.

Vinay believes the injections to be more effective and more immediate in their action when they are made early and at the time of the evening when there is a spontaneous rise in the temperature. Local treatment, curettage, and antiseptic washings are not to be neglected.

In every case except three, the degree of temperature and the frequency of the pulse were reduced after each dose of serum—in from six to twenty-four hours. The temperature in Case I fell from  $104^{\circ}$  to  $102^{\circ}$  in six hours after ten cubic centimeters of the serum (Pasteur Institute) had been administered, but it rose to  $103^{\circ}$  eighteen hours later. A second dose, of twenty cubic centimeters, reduced it to normal in ten hours, and it remained so. In Case III the temperature followed an exceptional course: after a single dose of thirty-five cubic centimeters (Ruffer's serum) it fell from  $104.4^{\circ}$  to  $104^{\circ}$  in six hours; at the twelfth hour (midnight) it rose to  $105^{\circ}$ , but at the eighteenth hour it fell to  $102^{\circ}$ , and at the twenty-fourth hour to  $99.2^{\circ}$ , and remained under  $100^{\circ}$  from this time onwards. This was the only instance in which a rise was observed after an injection. In three cases the temperature fell to normal in twenty-four hours. The pulse-rate varied with the temperature.

Two of the cases proved fatal. The first received a daily injection of twenty cubic centimeters (British Institute) for three consecutive days, with no observed benefit; the patient died on the fourteenth day, the fever remaining high to the last. With regard to this case, it was probably one of streptococcus infection, and had a larger initial dose been administered a different result might perhaps have been obtained; but if it was a case of staphylococcus infection, of course no benefit could be expected. This shows the supreme importance of a bacteriological diagnosis. The latter case, however, stands in a different light. Here a bacteriological examination had been made, and the case undoubtedly was a true example of streptococcus infection—streptomycolosis. A dose of ten cubic centimeters of serum (Marmorek) was injected on the fourth, fifth, sixth, and seventh day after confinement, and by it the temperature was reduced to normal on the ninth day. On the evening of this day, however, the patient was seized with bilious vomiting and meteorism. The next day she was much worse, developed uncontrollable vomiting and became semi-comatose, and died on the eleventh day, the temperature remaining low to the end. The serum was effective in reducing the temperature, yet the patient died two days later during convalescence. Gaulard, after the post-mortem examination, attributed her death to the use of too much serum. The total amount injected was forty cubic centimeters (Marmorek), spread over

four days. In view of his own experience the writer cannot agree with Gaulard, as in Case IV he injected sixty cubic centimeters (British Institute) during three days, and Kennedy used eighty-five cubic centimeters in two days, both cases recovering. There may, of course, be a difference in the strength of the fluids used. This emphasizes the desirability of bacteriologists adopting a uniform system of standardizing their serum.

An erythematous rash appeared on the chest, abdomen, and extremities, in two cases. It was of a fleeting character, and disappeared in the course of a few days without calling for any treatment.

Patchy pneumonia of the base of each lung complicated Case II. The first and second injections of thirty cubic centimeters were made on the eighth and twelfth days respectively. The temperature fell after each. On the seventeenth day there were signs and symptoms of pneumonia. During this attack the temperature ran a fluctuating and exceptionally high course, being  $106^{\circ}$  on the twenty-first and  $108^{\circ}$  on the twenty-third day. The attending physician looked upon the serum with suspicion, and feared it was the cause of the pneumonia; it was supplied by Dr. Ruffer. Is it possible that the serum, through defective filtering or otherwise, contained living streptococci? Might a serum containing living germs, or free serum, give rise to patchy pneumonia in a puerperal patient with a decided phthisical family history, such as Case II was? Finkler regards the streptococcus as the primary cause in the pathogenesis of certain cases of croupous pneumonia. Weichselbaum describes a *Streptococcus pneumonia* which, according to Mosny, is identical with the *Streptococcus pyogenes*. Harbitz describes five cases of non-typically coursing cases of croupous pneumonia, in four of which he found the streptococcus in pure cultures. Bulloch states that it is a frequent associate of other specific organisms in lung disease.

The serum was administered by subcutaneous injection into the areolar tissue of the abdominal wall; to avoid septic troubles, it was deemed essential to purify the skin as well as the syringe. In the foregoing cases these precautions were carried out as follows: the skin was washed with Johnston's ethereal antiseptic solution of soap (P., D. & Co.'s), then for two minutes with perchloride-of-mercury lotion 1:1000, and finally dusted with boric-acid powder. The syringe used was Debove's, of the capacity of ten cubic

centimeters; it was taken to pieces and placed in a pie-dish, which was boiled in a clean saucepan for fifteen minutes at the patient's home. Ten cubic centimeters were injected into each puncture, three such punctures being made for a dose of thirty cubic centimeters. In no instance was there local trouble.

The question of a maximal dose beyond which it is unsafe to go has not yet been settled; nor, indeed, are supplies of serum derived from different sources, or from the same source at different times, guaranteed to be of uniform strength. In the interests of clinicians it is desirable that a uniform system of standardizing be adopted by bacteriologists, and then clinical observers will be better able to agree as to what the maximal and submaximal doses should be. At present the practitioner has to rely for guidance upon the instructions which accompany each supply, and these vary with their sources. The largest dose which the author injected was thirty-five cubic centimeters; Kennedy injected forty-five cubic centimeters; the serum used in each case was Ruffer's. Better results were found after a large than after a small initial dose. His experience encourages the use of a maximal initial dose, to be followed, if necessary, by smaller doses at intervals of twelve or twenty-four hours. The British Institute of Preventive Medicine fixes the initial dose at twenty cubic centimeters, followed by another of the same amount if the temperature has not fallen. Bulloch states that much larger doses can be given with safety: ten cubic centimeters of his serum injected into rabbits caused no bad symptoms.

What cases are suitable? Puerperal infection may be independent of streptococci. According to Bulloch, recent research shows that a puerperal fever may be set up by the gonococcus (Krönig), the *Bacillus coli communis* (Marmorek), the Talamon-Fraenkel coccus, and the staphylococcus. In the majority of instances, however, puerperal fever means infection of the genital canal, and ultimately of the whole system, with the *Streptococcus pyogenes*. There is produced a septicemia—using the term in the sense in which it was originally employed by Koch, namely, a condition of microbic blood-infection where the microbes multiply in the blood and cause a rapidly fatal disease. The microbe at work most commonly is the *Streptococcus pyogenes*, and the type of infection strepto-septicemia, or, in the language of the bacteriologist, strep-

to-mycosis. It is in this class of cases only that the antistreptococcic serum is of value; the serum is specific against the streptococcus only, and attempts to cure staphylo-septicemia or infection caused by any other germ will not be successful. The combination of symptoms found in cases of severe puerperal septicemia point to a streptococcus infection, but in the absence of a bacteriological examination one cannot be certain. The streptococcus infection is at first essentially a local disease; it is later that it becomes a blood-infection. Therefore local treatment, antiseptic douches and curettage cannot be dispensed with, but must be carried out in conjunction with the serum, which comes into play when the germs have passed into the general circulation, annulling their action and toxin, and obviating the organic degenerations which are beyond local control.

*THE ACTION OF HYDROBROMATE OF SCOPOLAMINE UPON THE IRIS AND CILIARY MUSCLE.*

In the *American Journal of the Medical Sciences* for September, 1896, OLIVER sets forth the results of his investigations into the mydriatic action of hydrobromate of scopolamine.

A single instillation of  $\frac{1}{4}$  grain produces mydriasis in eighteen minutes, and full ciliary paralysis in twenty-three minutes. In every instance the pupil is fully dilated. The total ciliary paralysis and the pupillary dilatation are maintained for twenty-four to thirty-six hours. Accurate observations made several times daily prove that the diameter of the pupil becomes normal again in about seventy-two hours, and the power of the ciliary muscle is re-established in about ninety-six hours.

During the course of experiments with the drug it was noticed:

At the beginning of a few of the examinations there was a slight sense of conjunctival astringency, which in a couple of instances amounted to a stinging sensation.

There were no appearances of constitutional disturbance; care, however, was taken in every instance to prevent the passage of any of the liquid into the lacrymal passages.

In no instance was any apparent increase of a choroidal disturbance produced by the employment of the drug.

The early and complete paralysis of the ciliary muscle that can be obtained by the single instillation of  $\frac{1}{4}$  grain of hydrobro-

mate of scopolamine, and the rapid and full return of the action of the muscle, render this drug in this amount the most efficient and the most valuable cycloplegic that can be used for the proper determination of the total amount of ametropia.

The comparatively rapid return of the pupil to normal width proves the drug to be less objectionable than those drugs which, by reason of necessarily greater strengths to afford proper cycloplegic work, give more permanent mydriasis.

The perfect freedom from injurious constitutional effects when the amount named is used renders the drug absolutely safe for employment in all cases in which total cycloplegia becomes necessary.

*CHLORATE OF SODIUM IN THE TREATMENT OF CANCER OF THE UTERUS.*

E. DUVRAC, in a thesis fully analyzed in *La Semaine Médicale* of July 15, 1896, describes a method first used by L. Boucher, of Rouen, as a palliative of uterine cancer, with good results. It consists in the internal administration of chlorate of sodium in the manner in which Brissaud employs that drug in the treatment of cancer of the stomach, combined with the local use of the same substance as a dressing at the neck of the uterus. Internally it is given as follows:

- ℞ Chlorate of sodium, 5 drachms;  
Syrup of orange flower, 8 drachms;  
Distilled water, 3 ounces.

Mix. Two to eight tablespoonfuls to be taken daily.

It is well to make the patient begin with two tablespoonfuls a day, and to increase the dose rapidly up to a total amount of 128 grains of chlorate of sodium in the twenty-four hours. For local application the following powder is used:

- ℞ Chlorate of sodium,  
Subnitrate of bismuth, of each, 2½ drachms;  
Iodoform, 1 drachm.

Mix.

A small quantity of this is applied on a tampon to the cervix. Strips six inches wide and two inches long of sterilized tarlatan, impregnated with 1 part of iodoform, 20 parts of chlorate of sodium, and 20 parts of glycerin, may also be used. These are squeezed out, then cut into pads about four inches in length, and tied round the middle with a silk thread, with which the tampon can be removed from the vagina; each of these pads contain about fifteen grains of

chlorate of sodium. If symptoms of iodiform poisoning occur, tampons of salolized cotton, steeped at the time of dressing in a twenty-per-cent. watery solution of chlorate of sodium, should be substituted for those described. Lastly, a vaginal injection of a quart of boiled water, holding in solution 150 grains of chlorate of sodium, should be given every day.

Under the influence of this treatment, metrorrhagia and fetid discharge diminish and almost completely disappear; the pain ceases, so that morphine injections, which were previously necessary, can be dispensed with; the puffiness of the cervix diminishes, the ulcers cicatrize, appetite and digestion are restored, and the general condition improves. The effect of the treatment, however, is purely palliative, for the state of things becomes as bad as before if the dressings are discontinued, and the disease goes on unchecked in the deep parts which are not reached by the chlorate of sodium. Nevertheless, the method gives great relief and prolongs life. Thus, in the first case treated in the way described by Boucher, in which inoperable cancer of the uterus, which had already invaded the pouch of Douglas, coexisted with carcinoma of the stomach, the patient was kept alive in a fairly comfortable condition for three years.—*British Medical Journal*, Oct. 31, 1896.

#### ENDO-VEINUS INJECTIONS OF ARTIFICIAL SERUM IN ACUTE PNEUMONIA.

BASSI (*Gazzetta Degli Osped.*, June 6, 1896) reports six cases of severe acute pneumonia treated after the method of Galvagni—that is, by endo-venous injections of a solution of chloride and bicarbonate of sodium. In each case the pneumonia was double and of a grave type; of the six cases, five recovered and one died, and at the necropsy double broncho-pneumonia, right lobar pneumonia, and acute nephritis, in addition to an old stenosis, were found. With regard to the other cases, the author believes the treatment was of material service. The best time to give the injections is about a day before the expected crisis, or when the pulse becomes intermittent, or, in fact, upon any grave alteration in the condition of the patient. A small preliminary bleeding is useful. Whether the treatment acts by preventing coagulation of the blood, by oxygenating (through the incision) the venous walls and reflexly acting on the circulation, or in some

less known manner, the author is unable to say, but from his clinical experience in its use he feels justified in strongly recommending it for further trial. In a foot-note he refers to two other cases in which it was tried by him with success.—*British Medical Journal*, July 18, 1896.

#### AN OINTMENT FOR HEMORRHOIDS.

*La Médecine Moderne* of November 4, 1896, states that MONIN has employed the following formula with advantage in the treatment of this condition:

- ℞ Camphorated lanolin, 2 ounces;
- Castor oil, 3 drachms;
- Precipitated chalk, 1½ drachms;
- Hydrobromate of cicutine, 30 grains.

#### THE MIXED TOXINS OF THE STREPTOCOCCUS OF ERYSIPELAS AND THE BACILLUS PRODIGIOSUS IN THE TREATMENT OF MALIGNANT TUMORS.

COLEY, of New York, who has done so much good work in this line, contributes a paper to the *American Journal of the Medical Sciences* for September, 1896, in which he reasserts the value of this mixture of toxins in the treatment of malignant tumors. In most cases of carcinoma (including epithelioma) the effect is slight; in sarcoma it is most marked, but varies with the different types, the spindle-celled form showing by far the greatest susceptibility. The toxins exert a systemic as well as a local influence, but should be used only in clearly inoperable cases, or after primary operation to prevent recurrence. The results will vary greatly with the strength of the preparation, the most virulent cultures giving the best results.

#### SUBLIMATE INJECTIONS IN PERNICIOUS ANEMIA.

PATERA (*Riforma Medica*, May 23, 1896) reports the case of a lady, aged thirty-three, seen by him in January, 1895, with a history of severe anemia, fever, vomiting, insomnia, and extreme debility of a year's duration, attributed to severe uterine hemorrhage in the early part of 1894. The usual remedies were tried, but with very little success. The red blood-corpuscles were very much diminished in number. There was no albuminuria and no hematuria. Some blood was vomited on one or two occasions. Temporary improvement followed the author's treatment,

but when next seen, in December, 1895, the patient reported herself no better. Daily injections of five milligrammes of sublimate were then given for the space of two months, with excellent results: the anemia disappeared, and the patient radically improved, put on flesh, lost her palpitation, giddiness and sense of fatigue, and felt well in every way. The author refers to another case of severe anemia successfully treated in the same manner. It raises the question whether pernicious anemia may not be due to some hitherto undiscovered germ which is killed by the germicidal action of the sublimate.—*British Medical Journal*, July 18, 1896.

#### POISONING BY CHLORATE OF POTASSIUM.

FELLER (*Med. Corr.-Bl.*, Stuttgart, bd. lxxvi, No. 22) relates that a nervous but otherwise healthy woman, suffering from heartburn, took, by mistake for bicarbonate of soda, a heaped teaspoonful of chlorate of potash, and again half an hour later the same quantity. She was soon seized with violent vomiting and severe abdominal pains, especially about the kidneys, followed by strangury, anuria, and cyanosis of the extremities. Her skin was cold, pulse almost imperceptible, heart's action irregular, respiration slow; but her intelligence was unaffected. Under artificial warmth and cardiac restoratives the pulse improved, and the next day she passed a small quantity of highly albuminous bloody urine after severe nephritic colic. She could retain nothing on her stomach, but was given nutrient enemata, and on the third day the urine, though still scanty and passed with pain, was less albuminous, but the heart's action remained irregular. On the eleventh day, against the doctor's order, she got out of bed, fell down insensible, and very soon expired. No necropsy was permitted.—*British Medical Journal*, Sept. 12, 1896.

#### HEMATOPORPHYRINURIA.

KAST and WEISS (*Berliner Klin. Woch.*, July 13, 1896) refer to researches into this subject, and especially to those of Stokvis. This writer concludes that in rabbits hematoporphyrinuria is readily produced by the administration of sulphonal; and that the cause lies in the extravasation of blood into the mucous membrane of the stomach and duodenum. Kast has repeated the experiments, in which neither a single lethal dose, nor yet repeated doses

to the point of poisoning, produced a trace of hematoporphyrinuria. In the urine of rabbits, however, a markedly dark brown color of urobilin was noted, and in a few cases a faintly red color simulating that of hematoporphyrin. On further examination this latter was proved not to be hematoporphyrin. The authors then refer to the extravasations of blood into the stomach and duodenum; these occurred in about twenty-five per cent. of their experiments. They have found these extravasations in animals not treated with sulphonal, and believe that very slight causes will produce them. There was no relation between the extravasations and the amount of color in the urine. The authors have never been able to obtain hematoporphyrin from blood and sulphonal, whatever process was adopted. They still maintain that sulphonal in medicinal doses is a harmless remedy. The red coloration noted in some twenty-five out of one hundred experiments on rabbits was undoubtedly due to some change in the blood, but that was only produced by large doses. In dogs no foreign coloring matter was noticed in experiments extending over long periods of time. Under certain pathological conditions, and especially in anemic women and in obstinate constipation, there exists a loose combination of the blood-pigment. If in such cases immoderate doses of sulphonal are given, hematoporphyrin may be excreted in very acid urine; if the sulphonal is still used, threatening symptoms supervene. The authors draw attention to the rarity of cases in which hematoporphyrinuria has been noted. These results are also borne out in the case of trional, in which even the so-called cumulative action does not exist.—*British Medical Journal*, Oct. 10, 1896.

#### COCAINE POISONING: MAGNAN'S SYMPTOM.

RYBAKOFF, at a meeting of the Neurological Society of Moscow (*Neurolog. Centralblatt*, August, 1896), insisted on the diagnostic value of the symptom of chronic cocaine poisoning described by Magnan. This is an hallucination of common sensation: the patient complains of feeling some foreign body under the skin. In some cases the foreign bodies felt were like grains of sand, in others slightly larger; generally they were described as more or less rounded, and gave rise to complaints of microbes, worms, crystals, etc., situated just under the skin. While other symptoms of chronic cocaine poisoning occur

also in alcoholism and with other poisons, Magnan's symptom seems to occur only with cocaine. It has therefore a real diagnostic value, especially in cases where the patient is unwilling to admit having used cocaine. Where cocaine is extensively used in surgery and dentistry, the appearance of Magnan's symptom is a valuable indication for the immediate cessation of the drug. Korsakoff reported a case in which a woman suffering from multiple neuritis complained of "worms in the skin." On inquiry it was found that vaginal tampons containing cocaine had been freely used. The omission of these was followed by amelioration of the symptom.

#### *A DISCUSSION ON THE TREATMENT OF CARDIAC FAILURE.*

At the recent meeting of the British Medical Association, September 19, 1896, GRAINGER STEWART remarked that in the treatment of heart disease, among all the agents at our disposal, probably every one will agree that the most important is rest. In hospital cases we often obtain by this means alone most satisfactory results. The change which it effects in the cardiac muscle is of itself sufficient to bring out the most striking improvement. The heart, damaged or overtaken, has been carrying on a labor to which it was becoming daily more unequal. The burden of extra work is removed from it, and thereby it recovers tone. Even in the case of a professional man, whose work is to a large extent mental and therefore cannot be estimated by the foot-pound as in the case of the laborer, rest from work is of the greatest importance. After hours of intense mental effort, the heart becomes exhausted and cardiac symptoms more pronounced. When such a patient gives up work for a time and rests in bed, or goes to the country, or goes abroad, as, for example, to Nauheim, this element of rest from effort must be recognized as very important.

Stewart has found, however, that it is the rest from manual work that tells most favorably, and that, good as rest is for all heart cases, it is much more effective in these than in any other; for by the time that a man who leads a comparatively easy life begins to exhibit the general symptoms of cardiac failure his cardiac muscle is, as a rule, so much deteriorated as to be less capable of a rally than that of the laboring man exhibiting corresponding symptoms.

Second in importance is perhaps the ele-

ment of hope. When a patient knows himself to be suffering from formidable cardiac disease, and daily feels the discomfort and miseries attendant upon his cardiac failure, he is apt to be gloomy and disheartened; and this damages the organ in a way that we cannot at present fully explain. If such a patient becomes persuaded that he may recover, and that good compensation may be established, he becomes more hopeful about himself, and his heart receives a corresponding benefit.

Next in order ranks diet. Some cardiac patients benefit by an increased allowance of nourishment, some by a diminution of the amount, and many by an alteration of its quality. Among hospital patients it is not uncommon to find that the diet is largely composed of bread and butter with tea, the latter being used too strong and otherwise badly prepared; little butchers' meat can be obtained, and that little is often badly cooked. When such a patient is put upon a good and sufficient nitrogenous diet, with an adequate supply of butchers' meat, corresponding benefit inevitably results. In many of our cardiac cases occurring in private practice the supply of butchers' meat and other nitrogenous material has been beyond the necessities of the organism, and the heart has been in consequence debilitated from the undue supplies of nutritive material. In such a case the reducing of the dietary to that which fits the normal requirements of the system is attended by striking benefit. Many cardiac patients take far too much liquid, especially with or soon after their meals. Such a habit interferes with digestion, and also tends to keep at a high level the volume of the blood, and thereby to render the circulation more difficult; but probably more important than either of these is the tendency to increased obesity, which must not only render the heart's work more arduous, but interferes with the nutrition of the cardiac muscle by increasing its load of fat and interfering with the nutrition of its muscular fibres. Many a cardiac patient begins to show improvement from the time that he diminishes the use of his beverages, and of soups and other liquids at meals, and approaches more or less closely to the dry diet which was so strongly recommended by Sir Andrew Clark and by Professor Oertel of Munich.

Along with diet it is necessary to consider the use of alcohol—that is, the question of its habitual consumption as an article of diet. Any excess, even habitual slight excess, is to be strongly deprecated in all cases of threat-

ening cardiac debility. Its use in any form which is unsuitable to the stomach, giving rise to dyspepsia and secondarily disturbing the heart's action, must, of course, be forbidden. But its employment in moderate doses is of great service in cases of cardiac debility, and especially in such debility as we have seen of late years following influenza or diphtheria or any other acute exhausting disease, as well as in the advancing cardiac weakness so common in later life. The best form of alcohol is in most cases whiskey, and the dose may vary from two drachms to two ounces, taken once or twice, sometimes even three times, in twenty-four hours; but the amount for habitual use should never exceed four ounces in that time. It should always be taken with food, and if apart from the ordinary meals, should be mixed with milk or, what is better still, milk with beaten up white of egg.

Patients vary considerably in regard to advantage or disadvantage from the use of tea, coffee, cocoa, and other non-alcoholic stimulants, and the condition of each patient must be watched in relation to their use; but of course any excess in the employment of any one of them is very apt to disturb the action of the heart. This is especially the case if they are taken strong and towards bedtime.

In this connection also the writer refers to the influence of tobacco. It is best to discontinue it altogether when any cardiac debility exists, and if it is to be employed at all, it must be in extremely moderate quantities and after food.

According to the writer's experience the most valuable cardiac tonic is digitalis. It is certainly capable of improving the heart's contraction, rendering the systole more firm and sustained. It frequently steadies the pulse, removing irregularities of rhythm and of strength, and rendering it slower as well as firmer. It leads to relief of dyspnea and other pulmonary symptoms, removes dropsical effusions by promoting diuresis, and similarly, although to a less marked extent, removes other results of backward pressure, and under its use the dilated heart diminishes in bulk and the organ returns more readily to its natural size, compensation being gradually established.

The mode of action of digitalis may now be regarded as fairly definitely settled. It influences mainly the muscular tissues, both striped and unstriped, although it may also owe some of its usefulness to minor effects exerted upon and through the vagus. Of all

the muscular tissues, it acts chiefly upon that of the heart, next upon the unstriped fibres of the arterioles and the alimentary tract, and least upon the skeletal muscles. Effects upon the last named could only become prominent if a fatal dose had been administered; indeed, they are scarcely ever so in men, although readily demonstrable in the frog. But the fibres of the alimentary tract often give token of disturbance by the vomiting and diarrhea which the remedy produces; we may then conclude that we are giving more than is needed for action upon the heart. As to the precise effect upon muscle fibres, Professor Schmiedeberg has shown that digitalis renders muscular elasticity more perfect, so that each fibre extends more completely, and increases contractility, so that in contraction each fibre returns more perfectly to its minimum length. In accordance with this the heart is found to expand more fully and to contract more perfectly, and so both diastole and systole are more deliberate, especially the former. Digitalis possesses a greater power of contracting the arterioles than any other medicine of the group to which it belongs.

Theoretically it seems reasonable to think that its power of contracting the arterioles must be attended with disadvantages, inasmuch as it necessarily throws greater work upon the ventricle. Stewart has never been able to trace clinically evidence that this is so. He has often given nitrites along with digitalis, with the view of combating such a tendency, especially in cases where the heart-failure was associated with cirrhotic Bright's disease or with sclerosis of minute vessels—and, he thinks, with good effect, although he admits that experiments on animals have failed to confirm the value of such a plan of treatment. A really important consideration is that of the gastro-intestinal disturbance, the nausea, the vomiting, the diarrhea, which are not infrequently produced. This disturbance may be obviated, as we all know, by giving the digitalis in various forms and in various combinations; but, even with these precautions, we are occasionally obliged to abandon the remedy altogether. Our experience also teaches us that digitalis sometimes fails to rouse the heart to more vigorous action, and that its effects cannot be very rapidly brought about. A day or two generally elapses before we see the distinct effect; but, on the whole, it is the most reliable drug of the series, so far as Stewart's experience goes.

Next to digitalis he places strophanthus, for our knowledge of which we are almost entirely indebted to Professor Fraser, from whose researches it appears that it acts directly upon the muscular tissue of the heart, increasing contraction. He has found that when a solution containing one part of a dry alcoholic extract in 10,000,000 parts of liquid is perfused through the living heart of a frog, the heart's action is arrested in extreme systolic contraction in about fifty minutes; and when the solution is one part of extract in 5,000,000 of liquid, such extreme contraction of the cardiac muscle is produced that relaxation only occurs with post-mortem decomposition. But though acting so powerfully and with such rapidity upon the cardiac muscle, it has, according to Professor Fraser, little influence upon the muscular fibres of the arterioles. Other observers, especially Professor Kobert of Dorpat, and Dr. Thomson—who, although bearing an English name, practices in Russia—maintain that it does contract the arterioles of mammals, although not those of frogs. It would thus appear, theoretically, that strophanthus ought to give better results than digitalis; but this is not the writer's experience of it clinically, for its results have not in his hands been equal to those of digitalis. He has sometimes thought this might be due to the supply of strophanthus not being of so good a quality as that of digitalis; and that Professor Fraser's results with his own drug, so greatly surpassing the results which Dr. Balfour and the author were able to get, was due to the fact that he worked with a preparation from his own laboratory, which may reasonably be supposed to have been of better quality than that found in the ordinary market. But there is one consideration which makes the author doubt whether this is the whole explanation—namely, that unquestionably strophanthus is of greater service in an emergency, and helps the heart more rapidly than digitalis can; and this he found with the ordinary drug as sold in the market. This is a point of immense importance, which must always be kept in view in cases of urgently threatening cardiac failure.

Although on the whole inferior to digitalis except in this one particular, the results of strophanthus have in the writer's hands corresponded essentially to those produced by digitalis; and often when digitalis has failed to suit the stomach, he has with good result fallen back upon strophanthus. He points out, however, that in a certain proportion of

cases strophanthus disturbs the stomach more than digitalis does, and that he has sometimes had to discontinue the medicine for this cause.

With the other direct cardiac tonics he has had less experience, although caffeine has sometimes proved very serviceable by itself and in association with other drugs. Its action is, however, as was pointed out by the late Dr. Brackenridge, from his clinical observations, rather a direct one on the kidney than one upon the heart—an observation which has been confirmed by Dr. Gram of Copenhagen, and by Professor Schroeder of Heidelberg, who demonstrated conclusively, by experiment and otherwise, that caffeine, theobromine, and its more soluble preparation diuretin (which is a double salicylate of theobromine and sodium), stimulate the cells of the kidney and increase the urine, and only in a minor degree act upon the heart. At the same time, he warns against diuretin—that in his hands it has not proved very helpful in cardiac cases. The author has found nux vomica and strychnine of special service in cases where the other remedies are not well borne; and in all instances they may be given as adjuvants with much advantage. It appears to be demonstrated that they act in a marked way on the arterioles, producing contraction, and that the action is not directly upon the muscle, but upon the vaso-motor centre in the medulla, for it disappears when the cord is cut across in the upper cervical region. That they affect the heart also is proved by the fact that in cases of poisoning this organ may cease to beat and become fixed in a state of spasm—this through the vagus and cardiac ganglia.

The next group of cardiac remedies is that which acts by dilating the arterioles. Their effects, so far as we know, are purely mechanical; for dilatation of arterioles implies easier circulation, and less work for the cardiac muscles. Among these, for rapid action the foremost place is taken by nitrite of amyl, and its value in this respect has been universally recognized since the days when Dr. Lauder Brunton, as resident physician in the Royal Infirmary, Edinburgh, demonstrated its action in cases of angina pectoris. But for prolonged effect the author gives a foremost place to sodium nitrite and nitroglycerin: both of these have produced in his hands the best results, more especially in cases of sclerosis of blood-vessels, and of diseases of the aorta and of the aortic valves.

One other remedy requires to be mentioned, although its mode of action, and even its precise effects, are much more difficult to gauge—iodide of potassium. So far as the writer's observations go, this drug in ordinary doses has no marked effect upon the size or the action of the heart. It may be held as proved that in ordinary doses it neither depresses the heart nor dilates the vessels; and yet in certain cases, and particularly those of chronic inflammation of the muscular substance of the heart, it appears to aid the action of cardiac tonics. Most probably it tells upon coexisting syphilitic or other lesions, and thus helps to bring about a favorable result.

We must now turn to the remedies which help the heart by influencing the secondary results of cardiac failure; and among these we have to speak first of the means of dealing with dropsy.

Measures directed to the improvement of the cardiac condition are commonly of service in regard to dropsy also. The use of rest, of dry diet, of passive exercise, and of cardiac tonics, often suffices to relieve the symptom. But, on the other hand, special diuretics are frequently required; and if these fail, it is necessary to relieve by mechanical means. The safest and easiest mode of doing this is by tapping the pleura. In a large proportion of cases of cardiac failure, hydrothorax occurs, and its amount is often out of all proportion to the dropsy elsewhere. Its presence, of course, greatly aggravates dyspnea and adds to the embarrassment of the heart's action; and the author has found that the removal of even a small quantity, say twelve or fourteen ounces, from a pleura, gives relief to breathing far beyond what one would naturally expect. It of course follows that the removal of a larger amount produces proportionally greater results. But not only is tapping of service by directly relieving the lungs and the heart; it also favors the efforts of nature to get rid of dropsy elsewhere, according to the law that when a certain amount of relief is afforded mechanically the emunctories have a better chance of dealing with the remainder. Twenty years ago the writer used to look with some dread upon tapping for mere hydrothorax, but now for many years the practice has been so common in his wards that every house physician has been accustomed to minutely examine and if necessary to explore the pleura in every case of cardiac dropsy, and to draw off whatever fluid he could. Often a very limited area of

dullness corresponds to a very considerable amount of fluid, as if the arch of the diaphragm had become depressed. Ascites often requires tapping, and the operation is followed by very good results, although it is both somewhat more formidable and less satisfactory than the thoracic operation.

With regard to draining the skin of the legs and of the scrotum by means of Southey's tubes, the author never has recourse to this method unless he feels himself absolutely compelled to employ it. The risk of unhealthy action among the devitalized tissues, even when the strictest antiseptic precautions are taken, is very considerable. And yet he has often known life to be prolonged by successful drainage by Southey's method.

Among subsidiary helps in the treatment of cardiac failure is that which is directed to secondary changes, functional or structural, in other organs.

The alimentary system shows sometimes an extraordinary tendency to gastric catarrh, constipation, or deficient absorption from the intestinal tract. While these are all relieved in a measure by treatment directed to the heart itself, direct treatment by stomachics, aperients, and other medicines, sometimes also by abdominal massage, proves very important.

The passive congestion of liver may be helped by the use of aperients, which relieve the portal system and bile-ducts, or by counter-irritation externally, especially in the form of the acid compress, and the internal administration of mineral acids with taraxacum.

The hemo-portal system frequently requires very special attention, not in respect of its glands, but of the deterioration of the blood. A diminution of red corpuscles is both a consequence and a further cause of cardiac failure; and the ordinary remedies, iron and arsenic, with their combinations, are often of service in these conditions. In every cardiac case it is desirable to know the proportion of hemoglobin and corpuscles, and whenever they tend to diminish we should try to bring them up by the usual remedies.

With regard to the respiratory system, besides attention to the conditions of the pleura we must in all cases of cardiac failure watch the lungs, and especially the bases posteriorly, for indications of edema. Whenever this occurs we should endeavor by rubefacients, and sometimes by stronger measures, to overcome the tendency, and should of course treat, in the usual way, any bronchitis

that may appear; for both edema and bronchitis tend greatly to increase the cardiac embarrassment. Paroxysms of dyspnea are very apt to occur during the night, the patient being suddenly seized toward early morning with great distress. This may be associated with edema of the lungs, but is not always to be accounted for in that way—it must be referred to the condition of the heart-muscle itself. The best remedies are alcohol, especially in the form of spirits, with hot water or with milk or soup; ether, particularly in the form of Hoffmann's anodyne; or in extreme cases subcutaneous injection of ether, strophanthus, or strychnine; counter-irritation over the heart and lungs, and cupping, are also very useful. In cases where there is sudden increase of dyspnea with lividity, whether due to acute inflammation in the respiratory tract or mainly to sudden cardiac failure, there is need for blood-letting; and he has often seen life saved by the prompt use of this remedy.

With regard to the integumentary system, the most important points have already been mentioned when speaking of dropsy, but massage of the limbs and bandaging from the toes upwards with a view of affording mechanical support are not to be overlooked when dropsy is threatening.

As to the urinary system, we must constantly watch for the appearance of albuminuria due to backward pressure, and when it appears should use non-irritating diuretics, push the cardiac treatment, and counter-irritate over the kidneys. Essentially the same rules apply when actual inflammatory change in the kidney is superadded.

The nervous system frequently requires close attention, especially for the relief of sleeplessness and pain. For the former, much benefit is often to be got from the administration of a few ounces of strong beef-tea, with or without a little brandy or whiskey, at bedtime. As to the medicinal hypnotics, the main point is to avoid remedies which depress the heart, such as chloral, and large doses of bromide of potassium. Opium, morphine, paraldehyde, sulphonal and trional have given the writer the best results, and he often employs chlorodyne—he has known a cardiac case have a dose of it every night for a year with much benefit and no unfavorable result. For the relief of cardiac pain the nitrites are most serviceable, but opiates also, and sometimes sedative applications painted over the skin, are followed by good results.

Whenever cardiac failure exists, the treat-

ment should be essentially the same, no matter what the lesion may be. He has never seen reason to condemn the use of digitalis in aortic cases, and the only conditions in which he is inclined to urge great caution with the use of cardiac tonics are those in which there is reason to believe the inflammatory process in the valves is still advancing, or there are inflammatory or degenerative changes in the fibres of the heart, whether dependent upon disease of the coronary arteries or not. In the advancing inflammatory conditions he prefers to avoid tonics and exercise entirely, to insist upon absolute rest, and to prescribe arsenic and the iodide of potassium, often with carbonate of ammonia, while in the degenerative changes in the heart he employs tonics and exercises with the most scrupulous watchfulness.—*British Medical Journal*, Sept. 19, 1896.

#### EXTENSIVE BREAST AMPUTATION.

TANSINI (*International Medical Journal*, November, 1896) holds that in the attempt thoroughly to remove all lymphatic glands which may possibly become involved, secondary to cancer of the breast, recurrence in the skin has been overlooked. He calls attention to the frequency of recurrence of this sort in the form of isolated nodules in or near the scar. In order to avoid such recurrence, he removes the overlying skin of the whole breast, and a strip about four inches wide from the breast into the axilla. To cover the defect, a flap is dissected from the back, with its pedicle near the axilla, and stitched in position over the wound.

#### SOME REFLECTIONS ON APPENDICITIS.

On the ground of an extensive experience LE DENTU concludes an instructive paper, read before the Paris Academy of Medicine, as follows:

While it is true that a large number of appendicitis cases should be treated by surgical means, there are some in which a definite temporary cure can be secured by internal medication. These comprise cases of threatening peritonitis or peritoneal septicemia.

There are some appendicitis cases which go on regularly to the formation of an abscess. Sometimes these are characterized by a frank inflammatory reaction; sometimes the phlegmasia is well localized to the cecal region; sometimes the malady runs a natural course without signs of impending danger,

and here it may be of advantage to allow the abscess to accumulate and become circumscribed before resorting to interference. The formation of the pus-collection is revealed by local signs (localized pain, a tumor of the form of a breastplate, or globular fluctuation) and general signs (increase of fever, more or less restlessness, followed quite often by a remission coincident with the arrest of pus-formation). In these patients early intervention is not without risk. It can result in a dispersion of the agents of infection confined to a limited area, and this result is more to be feared than the appearance of pus in the first few hours.

Surgical intervention becomes opportune and necessary when it is believed, from the signs given above, that a focus has formed. The operation varies in technique according to the situation of this focus. If situated directly beneath the abdominal wall, a simple incision of all the layers is sufficient. It is necessary to guard against the rupture of adhesions (except in cases where one has reason to suspect the existence of multiple foci), and the appendix should be left in place if it is not floating or easily detached, the operator confining himself to suturing any perforation that may be discovered. Tamponade of the abscess cavity and partial suture of the abdominal wall complete the operation. If at a later period an eventration should result, this will furnish an opportunity for searching for the appendix, when it will be possible to determine whether all or nearly all the adhesions have disappeared, whether the intestine has again become entirely free, and to adopt the proper treatment.

If the focus is deeply situated, the operation is more delicate and also more dangerous. To penetrate down to it, it is necessary to break up some adhesions, taking all known precautions for preventing soiling of the neighboring parts; in a word, to guard in every way against operative infection. The diseased parts should be isolated by a tampon. But in spite of the best selected measures, it may happen that the peritonitis will become general and death result. If performed early in the cases characterized by a frank inflammatory reaction, the operation cannot be considered as absolutely inoffensive, while if delayed until the time when an abscess has formed it is not entirely secure, for the above reasons. Among the cases which go on to pus-formation, there are, therefore, those which are benign on ac-

count of the anterior situation of the abscess, and those which are dangerous on account of its posterior or deeper situation. In the latter no regret need be felt for not having interfered early, since the initial symptoms are often not menacing.

In the following conditions surgical interference should be resorted to as early as possible:

(a) When the patient presents at the outset the symptoms of a general peritonitis, or when in the course of an appendicitis the signs of extension to the peritoneum manifest themselves. These cases should not be confounded with cases of simple tympanites, accompanied with a certain amount of tenderness at a distance, indicative only of peritonism or peritoneal irritation, without septic peritonitis, properly speaking.

(b) When depression manifests itself under one of the following aspects: absence of spontaneous pains, temperature normal or a little below, with a frequent and small pulse; diminished secretion of urine; abdomen not distended, but retracted by contraction; facies shrunk and sometimes betraying signs of suffering, color more or less dusky, bluish color of the extremities, especially of the nails; voice feeble; respiration a little accelerated, without being sighing.

It is always risky to abstain from operative interference in cases in which there is a recurrence of symptoms. Inasmuch as operations during the intervals between the crises give excellent results, the fundamental treatment of appendicitis should be to prevent these subsequent attacks. If one is not forced to operate by the recurrence of an attack, it is best, according to Roux, to wait five or six weeks, since at that time the adhesions formed by exudates have in general disappeared, the operation becomes extremely simple, there is every assurance of success, and the patient is once for all freed of a menacing danger.—*International Journal of Surgery*, September, 1896.

#### *PUNCTURE OF THE LATERAL VENTRICLES.*

At a meeting of the Medical Society of Heidelberg, Professor VON BECK presented three cases of cerebral affections attended with increased cerebral pressure, in which he had successfully employed puncture of the ventricles. On the ground of his experience he formulates the following conclusions:

1. In localized lesions of the brain with

symptoms of cerebral pressure, it is advisable, if possible, to effect a radical removal of the primary disease; as for example, in hematomata of the dura resulting from rupture of the middle meningeal artery, by evacuation of the blood, and in cerebral abscesses by extirpation.

2. In focal lesions (cerebral abscess and cerebral tumor) whose site cannot be localized on account of the absence of symptoms, or which are inaccessible to surgical treatment, and go on to the formation of chronic hydrocephalus internus, as well as in diffuse affections of the brain with rapid and marked exudation of cerebro-spinal fluid into the cerebral ventricles, it is necessary to remove the pathological product which produces the severe disturbances and thus relieve the compression of the brain.

3. This relief of pressure is secured by evacuation of the accumulated cerebro-spinal fluid by puncture of the lateral ventricles.

4. The preliminary trephining should be performed in the region of the suspected site of the primary lesion, and, if possible, by the osteoplastic method, in order to gain extensive view of the interior of the skull, and to leave behind as small an osseous defect as possible. At the margins of the bone-flap, in the vicinity of the place of cerebral puncture, a small perforation is made extending through the scalp, for the purpose of facilitating any subsequent punctures of the brain.

5. The ventricular puncture is practiced at a point of the brain superficies as free from vascular supply as possible and not comprising any cerebral centres: in the frontal region, between the second and third frontal convolutions, three centimeters above the supra-orbital margin; two centimeters laterally from the median line, directly backward to a depth of three centimeters; in the parietal region, three centimeters in front of the central convolution, two and a half centimeters laterally from the median line, outward and backward to a depth of four to five centimeters; in the temporal region, transversely through the temporal lobe, between the first and second temporal convolutions, two and a half centimeters above the base of the mastoid process, to a depth of three to four centimeters; in the occipital region, four centimeters above the external protuberance, three centimeters laterally from the median line, to a depth of three centimeters in an anterior direction. The aspirator needle should be of the size of a straw, having an attachment seven to eight centimeters long,

and connected with a syringe holding ten to twenty cubic centimeters.

6. Puncture of the ventricles, repeated on recurrence of the symptoms of cerebral pressure, is to be preferred to drainage of the ventricles, because the latter is attended with more risk of infection of the brain.

7. Ventricular puncture is far superior to lumbar puncture as recommended by Quincke, since by means of it it is possible to evacuate the chief site of accumulation of the pathologically increased cerebro-spinal fluid, and, unlike lumbar puncture, it does not remove fluid from the spinal canal alone in those cases where the communication between the fourth ventricle and the spinal canal is obliterated by tumors in the posterior portion of the cranial cavity or inflammatory lesions. By simply emptying the spinal canal of cerebro-spinal fluid, an arterial fluxion is induced which is transmitted to the brain and, in connection with the existing serous stasis, produces an increased transudation, and, in the absence of compensatory provisions for an efflux of the cerebro-spinal fluid, may increase the dropsy of the ventricles and rapidly lead to interference with the vital centres of the brain.

8. By means of ventricular puncture the dangerous pressure effects are at once removed, and, in cases of cerebral tumors, punctures repeated at certain intervals, whenever there is recurrence of the pressure phenomena, may materially ameliorate the distressing subjective disturbances, and prolong life. In cases of inflammatory hydrops of the ventricle, the puncture may even lead to a cure by establishing normal circulatory conditions and by inducing a retrogression of the inflammatory process.—*International Journal of Surgery*, September, 1896.

#### ISOLATED FRACTURES OF THE SACRUM.

These fractures are so infrequent and their literature so meagre that we may be pardoned for publishing a rather extensive synopsis of a lecture by Dr. A. CHIPAULT, chief of the surgical clinic at the Hospital la Salpêtrière in Paris.

Gaudier, in discussing the pathology of this class of fractures, describes two varieties: *First*, where the line of separation passes through the fourth foramina posteriorly and the third anteriorly, the fractured surface being quite oblique. This variety generally results from a blow or a fall on an ankylosed coccyx or on the lower part of

the sacrum. As a rule, the lower fragment is much displaced forward and upward, carrying with it the nerve-roots. *Second*, where the line of fracture is situated posteriorly on a level with the third foramina, extending on both sides up to the second foramina, then describing a curve and terminating in the sacro-iliac articulations. This variety is generally the result of a direct blow, such as the kick of a horse. The displacement is not so great, nor are the disturbances of the nerve-roots so pronounced, as in the first variety.

In the first form (inferior fracture) the lower border of the upper fragment is prominent; below it is felt a transverse depression somewhat concealed by the swelling of the soft parts. Further down the finger encounters the lower fragment. Crepitus can be easily detected. The anus is usually pushed upward and backward. Sometimes a large hematoma is formed, pushing the rectum forward, the blood subsequently invading the dependent parts around the anus. The finger introduced into the rectum will feel the lower fragment, and may be able to reduce it. In the superior fracture (second variety) the physical signs are not so well marked, the depression is not so great, nor is the finger able to reach the lesion so easily; as a rule, the traumatism is more severe, and the soft parts are much bruised or crushed, lacerations being frequently encountered.

In studying the literature of this subject, we find that the descriptions of the functional symptoms are, as a rule, very incomplete. Dufour gives us a graphic picture of these symptoms in one of his cases. The patient was a man forty-four years of age, who had fallen on the sacrum. He lost consciousness for a short time, experienced agonizing pains during three days, and when admitted to the hospital was found to be suffering from complete retention of urine and loss of sensation in the urethra. At the end of six weeks he was able to walk a short distance. Muscular strength was well preserved in the limbs, although the left calf had lost some of its rotundity. The patellar reflex was normal on the right side, decreased on the left, the tendo Achillis being in the same condition; there was no foot clonus. The sphincter ani had lost its contractility and was almost insensitive. There was also marked loss of sensation in the urethra, with slight incontinence of urine. The penis and scrotum were anesthetic, the anesthesia also affecting the internal and posterior regions of the left thigh.

Hammond, in his report of a case, mentions paralysis of the lower extremities, distention of the bladder, obstinate constipation, anesthesia of the vagina, sensation over the thighs almost normal, the right leg completely anesthetic, sensation diminished in the left leg. Tuffier furnishes a more complete description of a case observed by himself: The patient, a woman, thirty four years of age, had fallen from a considerable height. She exhibited paralysis and anesthesia of both legs, incontinence of urine, and constipation. Later she developed painful spasms of the legs and muscular atrophy. Four years later she became pregnant and gave birth to a living child. At times she suffered from severe pains and suppurating ulcers, principally over the right foot. Rectal and vaginal palpation revealed the existence of an unreduced fracture, with greater displacement on the right side. Her walk was difficult and feeble, knees weak, sensation lacking over posterior internal surfaces of thighs and legs.

The following is a *résumé* of a case reported by Church: The patient, a boy, nineteen years old, had fallen from a height of thirty-six feet. When examined, a large ecchymosis was discovered over the sacrum; the legs were paralyzed and anesthetic; there was constipation and retention of urine. For several weeks the patient suffered from painful crises in the legs, and then improved slowly. At the end of two years his condition was as follows: Standing difficult, with feet widely apart; constant oscillation while walking, with rotation of femurs; complete loss of sensation over buttocks, genitals, feet, and posterior surfaces of thighs and legs; pronounced atrophy of the glutei maximi; plantar reflexes abolished, patellar reflexes decreased.

Another case is reported by Chipault himself. The patient was a man, fifty-two years of age, who had sustained a fall from the fourth story of a building. After the accident he lost all motor power in his legs below the hips; complete retention of urine and constipation existed. Sensation was not tested. He improved very slowly, and after a time was able to walk with the aid of canes. When examined by Chipault after the lapse of fourteen years, he presented the following condition: Consolidation of the sacral fragments in a false position; incontinence of urine and feces; complete anesthesia of rectum and urethra.

The treatment of sacral fractures varies according to the complications. If not complicated with motor or sensory disturbances,

the surgeon should try to reduce the fracture by means of the finger cautiously introduced into the rectum; in recent fractures this is quite practicable; no operation is required. If there are symptoms of motor paralysis or loss of sensation, surgical intervention is imperative. If reduction by way of the rectum is found impossible, or the fracture does not remain reduced, an incision should be made and the apophysis united by sutures. Gaudier successfully operated in his case by making a crucial incision over the seat of the fracture and passing two silver wires through the fragments, while an assistant retained the latter in position with the finger in the rectum.

If the fragments are so impacted that the fracture cannot be reduced, it is best to perform a laminectomy in order to free the nerve-roots of all pressure. When the fracture is of long standing, reduction is no longer possible; but if not too old, improvement can yet be obtained by laminectomy, the cauda equina being carefully freed from cicatricial tissue. This was tried by Church in his case, which was complicated with a fistula. After the operation the fistula closed, and sensation returned to the legs, thighs, and anus, while the paralysis of the left leg almost disappeared. The favorable results derived from operative intervention in this case demonstrate that marked improvement can be frequently effected in this class of fractures even when the injury is of months' and years' duration.—*International Journal of Surgery*, September, 1896.

#### INJURIES OF BONES INTO JOINT CAVITIES.

STEWART L. McCURDY (*International Journal of Surgery*, September, 1896) says that compound fractures of bone into the joint cavities, or compound dislocations, if given thorough treatment at the time of the accident, are almost as promising as simple fractures into joints. In some cases, indeed, it is an advantage to have the joint open, so that the serum in abnormal quantities, blood-clots, fragments of bone, and injured cartilages, as in the knee, may be removed.

In the treatment of fractured patella it is now the practice to remove the synovia between the fragments by aspiration, or to make an opening below the patella to allow the fluid to escape.

Compound dislocations and compound fractures into joints, if they are treated with-

out suppuration, generally recover with functionally useful joints. Suppuration following such injuries, on the other hand, destroys the synovial membrane, and limitation of motion must be expected. Some cases recover with true ankylosis or bony union, and others recover with firm fibrinous or false ankylosis. The latter class of cases can generally be improved by passive motion.

Passive motion should not be instituted until all inflammatory symptoms have subsided and sufficient time has elapsed to insure firm bony union.

At the last meeting of the American Orthopedic Association, Dr. ANSEL G. COOK, of Hartford, Conn., discusses this subject at length, and summarizes by saying:

1. Bony or serious fibrous ankylosis is the result of injury and subsequent inflammation, and not of immobilization.

2. Early passive motion only disarranges the fragments of bone, thereby increasing the production of callus; irritates the injured ligaments; and, by increasing the inflammation, tends to produce the ankylosis it is thought to prevent.

3. Immobilization is useful only when active inflammation is present or until the ruptured ligaments or broken bones have thoroughly united.

4. The logical treatment of a fracture into a joint, therefore, should be rest and local applications to reduce inflammation; reduction of the fracture as early as possible, then immobilization until the bones and ligaments are united (from three to eight weeks or more, according to circumstances).

5. Passive motion, massage and use until the tissues become normal, or, if massage fails, complete rupture of all adhesions under an anesthetic, are indicated. The factors which will ultimately determine ankylosis are: the nature of the original injury, the character and duration of the subsequent inflammation, the destruction of bone and cartilage, cicatricial contractions of the soft tissues around the joint, and the age and condition of the patient.

*Case 1.*—C. W.; fracture of olecranon; seen two days after injury, the arm having meantime been dressed at an angle of 45°; it was at once dressed in complete extension, and kept there for seven weeks, when the splint was removed, and in another month the arm was perfect. Patient returned to his former occupation as locomotive engineer.

*Case 2.*—J. H. P. fell from a moving train and received a fracture of the olecranon,

quite similar to the preceding case. The physician who gave temporary relief dressed the arm at a right angle. Cook dressed it in complete extension and kept it there for six weeks, when the dressings were removed, and in ten weeks the patient returned to his former occupation as railway conductor, with a perfect arm.

The common practice of the average practitioner, in fractures into the elbow-joint, of applying dressings with the arm in a position of flexion, is a great mistake. Allis made a masterly advance when he advocated complete extension for the treatment of all such cases. Extensive injuries into joints may recover, with fair usefulness.

*Case 3.*—J. W., besides receiving two scalp wounds seven or eight inches long, sustained a fracture of the left humerus at two points and a compound fracture of the head of the radius, with about half of the articular surface of the bone detached. He also had a fracture of the ulna of the same arm, and a fracture of the right fibula. An occasional dressing was made of the various wounds. The arm was dressed in extension, and was kept in that position for about six weeks. Union of all these numerous fractures was prompt, and the patient returned to the coal mine in six months as a full hand.

*Case 4.*—G. L. G. had his right foot caught under a large stone as it was being lowered by a derrick. The weight was received on the outside of the foot gradually, and another stone near by held the leg almost perpendicular. When the member was examined, a complete compound dislocation between the astragalus and os calcis was found. The foot was turned out at a right-angle with the leg, the astragalus protruding completely through the wound.

Amputation is usually advised in such cases, but in this case it was thought best to make an effort at reduction, and if it should then be found that the blood supply was not entirely destroyed, an effort would be made to save the foot. After washing sand, etc., from the astragalus, and as near as possible securing antiseptis, reduction of the dislocation was accomplished. It was quite a task to make reduction, and it was only accomplished by using a very heavy bone-elevator as a sort of pinch-bar, over the astragalus and under the os calcis, thus throwing the margins of these bones free. After a long siege the wound was entirely healed; the ankle was ankylosed, but otherwise the foot is quite useful, and locomotion is not ungraceful.

*Case 5.*—J. L., aged twenty-four, a brakeman, suffered a compound dislocation of the second joint of the left middle finger, the joint surface being plainly visible. This wound was closed under antiseptic precautions, and healed promptly without infection. In two months motion was perfect.

*Case 6.*—M. B., aged fifty, was walking along the railroad, when a train backed up and knocked him down between the rails, the entire train passing over him. The arm being flexed, the elbow was caught under a wheel and the entire joint crushed, except the head of the radius. The case was seen a few hours later in consultation with Dr. Grove. As the circulation appeared good, it was decided to remove the detached pieces of bone, trim up the lower end of the humerus and upper end of the ulna, and drain and close the wound. The injury occurred on Monday. On Friday the drainage tube was removed; and on Saturday, the eighth day, the next dressing was made, and this was renewed once a week. The skin that was destroyed by the wheel came off as a dry slough. The wound healed promptly, without subsequent complication. One year after the accident the arm is almost as useful as before the bones were removed. With the arm hanging down, the forearm can be fixed to a right-angle. He is now working at his former occupation as a trackman, and suffers little inconvenience.

#### *A METHOD OF CLOSING THE OPENING AFTER GASTROSTOMY AND ENTEROSTOMY.*

C. J. BOND, in the *British Medical Journal* of July 4, 1896, presents the following technique suggested by reading Mr. Harrison Cripps's description of a method of temporarily closing gastrostomy and enterostomy wounds, which he found useful in permanently closing the same wounds. In April, 1894, in a case of pyloric stenosis, after failure of pyloroplasty he established a communication with the stomach in order to dilate with bougies the strictured pylorus. Later on it was necessary to close this somewhat large opening. An oval disk of sheet india-rubber, larger than the fistula, was coiled up and inserted in the way Mr. Cripps directs; before passing it into the stomach it was pierced by a double row of plated wire sutures, six or eight in number, each suture going completely through the disk twice, and forming a loop on the back. The free ends

were loosely held while the plate was let into the stomach, and after unfolding it was drawn up flat against the mucous membrane by the double row of sutures. The edges of the fistula were freshened, care being taken to cut away the mucous membrane. This can be done best by drawing it out and cutting it off all round, allowing it to shrink back again inside. Then, by means of a handled needle with a suitable curve, each wire was threaded separately and brought through the coats of the stomach and the abdominal wall from within outwards, close to the edge of the opening. In this way one row of sutures passes through one side of the opening, and the other row through the other; the edges can then be brought together and the sutures tied externally; the opening is thus effectually closed against leakage by what is practically a button suture, with the button within the cavity. Each suture can be cut and drawn out whole, and the plate allowed to drop into the stomach or intestinal canal. In the case referred to, the acid gastric juice dissolved the portions of wire in contact with the india rubber, which was thus liberated and vomited a fortnight later.

#### WARTY CORNS ON THE SOLES OF THE FEET.

C. S. EVANS (*British Medical Journal*, July 18, 1896) reports the following case: H. G., aged fifteen, came under treatment on November 9, 1895, lame in both feet and unable to walk without pain, owing to a crop of sixteen hard and very tender spots on one foot and six on the other. The largest and most tender in each foot was evidently a large wart, flattened by pressure and surrounded by a hard horny ring; the others looked like corns.

On cutting parallel to the surface, each showed from one to about twenty hypertrophied papillæ in section. After three weeks of daily applications, after a hot bath, of a saturated solution of caustic potash at first, afterwards of fuming nitric acid, followed by a coating of salicylic collodion, all the horny epidermis was peeled off or cut off, and two-thirds of the warts had disappeared. Another week of caustic applications at two or three days' intervals, by which some of the warts were destroyed to the extent of leaving small ulcers, sufficed to render the feet tolerant of pressure at any point, and walking was allowed for a fortnight, still using the salicylic collodion every few days (as

often as could be borne). After this the feet were said to be "perfectly comfortable," but there was still some excess of horny epidermis at and around the sites of a few of the warts.

Izal (1:400) was used in the baths, and there was no trouble from suppuration. The minute ulcers, when they occurred, skinned over in three days, being filled with airol and covered with collodion. Double woolen socks and three-per-cent. salicylic-talc powder were directed to be used for several months after.

The large number of warts in this position, not entirely confined to points of pressure, and the urgent need and satisfactory issue of treatment, seemed to render the case worthy of notice.

#### CONCLUSIONS AND SUMMARY OF RESULTS OF 118 CASES OF RUPTURE OF THE KIDNEY.

The total number of cases of rupture of the kidney, in greater or less degree, which appear in KEEN'S tables, is 118. Of these, one case was under treatment when reported, and the result, therefore, is not known. Of the 117 cases, 67 recovered and 50 died, a mortality of 42.7 per cent. From these, however, if we are to judge rightly of the mortality, the following seventeen deaths in which treatment was futile or impossible should be deducted: the other kidney absent, 1; both kidneys injured, 2; found dead, 2; died of other injuries in addition to the renal injury, 12; total, 17. This leaves a total of 100, of whom 67 recovered and 33 died, a mortality of thirty-three per cent. This, however, is more than the necessary mortality of this serious injury, provided it is properly treated. There were thirteen deaths in cases in which no nephrectomy was done; eleven of these died from shock and hemorrhage, and two from peritonitis in addition. There were also ten late deaths without nephrectomy, of whom all died from septic causes, excepting two, who died, one from continuous and the other from secondary hemorrhage. Had nephrectomy been done in these twenty-three cases, it is a fair presumption that ten of them would have recovered, which would have reduced the mortality to twenty-three per cent.

One of the most important questions, therefore, in connection with the treatment, is whether nephrectomy should be done or not; and the light cast upon this question by the statistics collected in these tables is very im-

portant. Eliminating the two cases of partial nephrectomy, which both recovered, there are twenty-two cases of nephrectomy with eight deaths, a mortality of 36.4 per cent.; there were ninety-five cases in which no nephrectomy was done, with forty-two deaths, a mortality of 44.2 per cent. This shows a difference of eight per cent. in favor of nephrectomy, though the operation is only done in the most serious cases.

The value of nephrectomy, especially of early nephrectomy, as a life-saving operation, is all the more evident when we remember that the large majority of the cases in which no operation was done were but slightly injured. If, then, these less serious cases show a mortality so much greater than the graver ones in which nephrectomy was done, it is evident that operation in many of the ninety-five unoperated cases in which the lesion was of a serious character would have saved many lives.

Keen endeavors also, by making an analysis of the cases, to determine the relative safety of primary as compared with secondary nephrectomy, and of the abdominal as compared with the lumbar operation.

He finds five cases of primary nephrectomy with one death, a mortality of 20 per cent.; and thirteen cases of secondary nephrectomy with five deaths, a mortality of 38.5 per cent., showing that secondary nephrectomy is nearly twice as fatal as primary.

As to the route of the operation, there were three cases of abdominal nephrectomy, of which one died, a mortality of 33.3 per cent.; and fourteen of lumbar nephrectomy, of which four died, a mortality of 28.6 per cent. The number, especially of abdominal nephrectomies, is, of course, too small from which to draw any rigid conclusion, but on the whole lumbar nephrectomy is the more desirable operation.

The causes of death are also very instructive. They may be tabulated as follows: primary hemorrhage and shock, 11; continuous hemorrhage, 1; secondary hemorrhage, 2; injury of other organs, 12; found dead, 2; absence of the other kidney, 1; peritonitis, 5; coma, 2; pneumonia and empyema, 1; supuration and exhaustion, 10; anuria, 1; nephritis, 1; uncertain, 1; total, 50.

If we group these under more general headings, it will be observed that by excluding the injuries of other organs (twelve), those found dead (two), the case of one kidney (one), and the uncertain case (one), we have thirty-four cases left, and of these primary,

continuous and secondary hemorrhage, combined with shock, destroyed fourteen; supuration, including peritonitis, destroyed sixteen; leaving coma, anuria and nephritis responsible for only four deaths. These figures emphasize what has been already stated, that the dangers of rupture of the kidney above everything else are hemorrhage and sepsis.

The duty of the surgeon, then, seems clear. Where the symptoms are threatening, especially if there is marked evidence of hemorrhage or probable danger of sepsis, an exploratory operation should be done immediately. Whether nephrectomy should be done, is to be determined by the conditions already stated. It is especially to be noticed that the great mass of recoveries in rupture of the kidney are the slighter cases; the graver ones do not recover, unless an operation is done. In any case, therefore, with severe or dangerous symptoms, the surgeon should lean towards exploration, and in severe laceration towards early nephrectomy. It will add little to the risk and will probably save a considerable proportion of lives.

A word only is necessary as to hydronephrosis and rupture of the ureter. There were six cases of pseudo-hydronephrosis (so called since it is outside of the pelvis of the kidney), of which five recovered, the single death being from inguinal abscess. In one case a nephrectomy was done, followed by recovery. In the other five, either aspiration or tapping was resorted to, with four recoveries and one death.—*Annals of Surgery*, August, 1896.

#### EXTRA-PERITONEAL EXPLORATION OF THE URETER FOLLOWED BY NEPHROLITHOTOMY.

PERKINS says he has found reports of but six cases of extraperitoneal uretero-lithotomy.

Of these six operations, one (Twyniam's) was preceded by an exploratory laparotomy through which a stone was located in the right ureter just below the brim of the pelvis, two inches from the bladder; three weeks later, after the laparotomy wound had healed, the stone was removed by longitudinal ureterotomy through an extraperitoneal incision in the right iliac region.

One (Cabot's) was a primary exploration and needling of the kidney through a vertical lumbar incision, with negative results; then at once an exploration was made downward along the course of the ureter, and a small,

hard mass detected about two inches below the kidney; a needle showed this to be a little calculus, and it was immediately extracted through a small longitudinal incision into the ureter.

In two cases (Ralfe and Godlee's and Fenger's) a primary lumbar nephrotomy was done, without finding a stone in the kidney; immediate exploration of the ureter downward detected a stone in the ureter, in the first case, two inches below the kidney, and in Fenger's case two stones were found one and a half inches below the kidney; in both cases the stones were removed by longitudinal ureterotomy.

One (Kirkham's) was an exploratory lumbar incision with palpation of the kidney, without finding stone; exploration of the ureter discovered a stone therein, half an inch above the crossing of the external iliac artery; it was removed by ureterotomy.

In one case (Briddon's) lumbar nephrotomy had been performed without finding stone in the kidney; four years later, lumbar nephro-lithotomy, with extraction of a stone from a large pus-cavity, into which the kidney had been converted; four months after this, nephrectomy; and four months later, exploratory laparotomy, which located a calculus in the ureter just below the brim of the pelvis; the stone was at once extracted through an extraperitoneal incision into the ureter.

Of the three recorded cases of intraperitoneal uretero-lithotomy, in one (Cullingworth's) the impacted stone, which could be felt through the vagina just above the bladder, was mistaken for a diseased ovary prior to the opening of the abdomen; in another (Arbuthnot Lane's) a primary exploratory lumbar incision showed the pelvis of the kidney dilated, but did not locate the stone, which was found through a laparotomy wound, eight months afterwards, in the pelvic portion of the ureter, from which it was extracted. In the third case (Robert's), catheterization of the ureter showed obstruction one and a half inches above the bladder; lumbar incision and renal palpation were negative, but through an incision into the dilated ureter, one inch below the pelvis, a rubber bougie encountered an obstruction ten inches farther down. Through the vagina could be felt what seemed to be a growth of the size of an English walnut, high up in the pelvis, behind the uterus and to its left; it was thought to be a small tumor pressing upon the ureter and causing a valve-like

stricture. Four months later a median laparotomy was done, and no tumor found; but on cutting through into the ureter and exploring it with a sound, a stone the size of a large olive pit was detected and extracted.

In several cases stones in the ureters have been successfully removed through an opening made in either the pelvis of the kidney or in the kidney itself, by pushing them up into the pelvis; but in these cases a primary examination of the kidney through a lumbar incision had been made, and, no stone being found in it, the ureter was explored, either through its renal orifice with a sound, or by palpation externally. And in one case (Hall's) this manœuvre was immediately preceded by an exploratory laparotomy.

From the histories of seven of these nine cases of uretero-lithotomy, in which either primary explorations of the kidney were made, or operations on the kidney were actually done, it is evident that the symptoms produced by the impacted ureteral calculus simulated those of a stone in the kidney itself.

In Perkins' case the converse of this was true. The symptoms caused by a renal calculus simulated those of an impacted ureteral calculus, and determined him in making a primary extraperitoneal exploration of the ureter rather than a primary nephrotomy.

An examination of the symptoms of stone in the kidney shows that they are very similar to those produced by stone in the ureter, with the exception of the location of the point of greatest tenderness to pressure. When the stone is located in the kidney or its pelvis, this point is generally found just below the twelfth rib, at the outer edge of the erector spinæ mass—in other words, directly over that portion of the kidney accessible to pressure. When a stone is located in the ureter outside of the true pelvis, the point of greatest tenderness is to be found either in the loin below the level of the kidney, or in the iliac region by deep pressure through the anterior abdominal wall over the course of the ureter, the most common location being about two inches above Poupart's ligament and two inches internal to the anterior superior spine of the ilium.

It is upon the location of this point of greatest tenderness that most reliance is placed in making a differential diagnosis; and that this is misleading in some cases is abundantly shown by the history of the following case:

Mr. B., aged forty-eight years; American;

married; a hotel proprietor for the past two years, but formerly an agent for a railway company. Family history negative, except that his mother died of diabetes. He kept a diary for many years, and has notes of numerous attacks of severe abdominal colic occurring since 1889. He always enjoyed good health until 1878, when he had his first attack of renal colic, which lasted for thirty-six hours and was followed by the expulsion per urethram of a very hard, smooth, white calculus of about the size and shape of a small white bean. There was no further trouble until September, 1889, when he had an attack of severe colic-like pain in the left iliac region, accompanied by nausea and vomiting, which lasted half a day. In December, 1889, he had another and similar attack. These attacks occurred for the next five years till in May, 1895, he had a severe attack, with convulsions, and was unconscious for about an hour.

In the left iliac region on deep pressure could be felt a cord-like structure, apparently about the size of a man's finger, extending from about the middle of Poupart's ligament vertically upward to the edge of the ribs. This was slightly movable under the fingers, and tender for two or three inches above the ligament; at a point about two inches above the ligament, and two inches internal to the anterior superior spine of the ilium, was an exquisitely sensitive spot, that could be covered with one finger-tip. There was no enlargement of the kidney, and it could not be felt. There was no particular tenderness over the kidney or in the lumbar region, though very deep, hard pressure over it caused slight pain. Exploration of the rectum and bladder gave negative results. The urine was slightly turbid, specific gravity 1.022, and of very strongly acid reaction; it contained a large trace of albumin, but no sugar. The sediment consisted of numerous crystals of oxalate of lime, a few red blood-disks, and a few pus cells, but no casts were found. The urine averaged about thirty-six fluidounces in twenty-four hours.

An oblique incision was made in the left iliac region, about five or six inches in length, having for its centre the most sensitive spot, which had before been marked on the skin. When the peritoneum was reached it was stripped off and rolled inward until the ureter was found attached to it. The ureter appeared to be of about the normal size, not dilated and enlarged. Careful palpation downward into the small pelvis behind the

bladder as far as the fingers could be inserted, revealed nothing abnormal, and the absence of enlargement of the ureter indicated that the trouble must be located higher up. The incision was therefore enlarged upward and backward, a few inches at a time, and the ureter followed upward throughout its whole length to the pelvis of the kidney, without finding any evidence of trouble in it. When the kidney was reached it was found to be of normal size and consistence, and without irregularities of surface, except at one place in the region of the pelvis, where there was a slight thickening with an abnormal amount of resistance to pressure. A needle introduced through the outer border of the kidney in a direction toward the pelvis, at once struck a stone with a click that could be heard by all present. A scalpel passed along the needle as a guide made an incision about an inch in length through the kidney substance, which was at once dilated by the finger until the latter touched a rough stone in the pelvis; this was grasped by a slender Wyeth hemostatic forceps and easily extracted. Exploration of the pelvis and calyces with the finger-tip failed to detect any other concretion. No probing of the ureter was thought necessary, as it had been carefully palpated throughout its entire length.

The history of this case affords the best possible corroboration of the well known surgical fact that a comparatively small, rough, movable stone in the pelvis of the kidney is capable of producing the most distressing and dangerous conditions. But why a stone so situated should produce a constant, localized, exquisitely sensitive point of tenderness at the middle part of the ureter, is not easily explainable. The fact that it did produce this effect must necessarily invalidate to some extent the chief diagnostic sign of a calculus impacted in the ureter, and brings up at once the question whether in all cases with symptoms pointing to stone above the bladder, unless the stone can be actually felt in the ureter, it would not be better surgery to first explore the kidney and work from above downward rather than from below upward. Certainly, no more positive indications of stone in the ureter would be likely to be found in any case than this one presented, and the operator believes that every surgeon in a similar case would be tempted to first explore the ureter as he did.

However, the result of this operation has somewhat shaken his faith in the value of the diagnostic symptoms of ureteral calculus, un-

less, indeed, this be the exception that proves the rule. However much we may desire to arrive at an exact diagnosis, it is well always to keep in mind the ratio of probabilities between two conditions, and to give that ratio its due weight in reaching a conclusion in cases where the signs and symptoms point to the lesser probability.—*Annals of Surgery*, August, 1896.

#### THE TREATMENT OF ABORTION.

McKEOUGH (*American Medico-Surgical Bulletin*, Sept. 12, 1896) states that the first question in the treatment of abortion is one of prophylaxis. If consulted by a woman who has had frequent abortions, a most careful investigation should be made into the past history of the person herself, and also of her husband, in order to ascertain the presence of any constitutional cause such as syphilis, rheumatism, or anemia. A search should be instituted for any local cause such as displacement, laceration of the cervix, endometritis, cervicitis, or pelvic adhesions, and, if discovered, appropriate treatment should be adopted. An abortion has been arrested even after threatening symptoms have manifested themselves, by replacing a retroflexed uterus, and the cases are innumerable in which a curettement and a trachelorrhaphy have brought about, not only restored health, but a pregnancy and its happy results.

A woman who aborts at the same period in several pregnancies, and in whom no disease of the uterus and its appendages or constitutional ailments can be discovered, should have absolute rest in bed at the approaching time. In these cases Waumann highly recommends asafetida, commencing with two three-grain pills a day, increasing to ten, then diminishing. It is in these cases, *abortion habitualis*, that the author believes viburnum to be of the greatest value.

In abortions due to disease of the placenta causing the intra-uterine death of the fetus, chlorate of potash, first introduced by Simpson, is of benefit.

For threatened abortion, reliance must chiefly be placed upon perfect rest and opium. Immediate confinement to bed in the recumbent posture should be insisted upon, on the first suspicious symptom showing itself, with the use of the bedpan when required. A hypodermic injection of morphine is preferred in most instances, but in some cases an opium suppository or an enema of laudanum may be the most desirable.

Opium is a most valuable remedy here: if given sufficiently early, it controls pain and hemorrhage, arrests uterine contraction, and prevents the expulsion of the fetal contents. If hemorrhage has been profuse and the patient shows the results of the loss of a large quantity of blood, opium is one of the best cardiac tonics; if the retention of the contents of the uterus is not possible, it will aid in the dilatation of the cervical canal and facilitate fetal expulsion.

The amount of hemorrhage, the severity and duration of the pain, and the degree of dilatation of the cervix, are the points to be taken into consideration in forming an opinion as to the preventability of the abortion. If any of these symptoms is pronounced, it is not safe to give a favorable prognosis; and if they are all present we cannot hope to arrest the expulsion of the ovum.

When abortion is inevitable, the patient must receive our earnest attention. If it be the result of natural causes, and the death of the ovum has occurred several days previous to its expulsion, it usually comes away entire, when the uterus will contract, the pain and hemorrhage cease, involution proceed normally, and the patient's condition soon be the same as before pregnancy. If the ovum is alive, or if the abortion be induced by mechanical means, as it is to be feared is too frequently the case, the fetus usually escapes, leaving the whole or a portion of the placenta and chorion inside.

If called to a case of abortion or threatened abortion, which upon examination is found to be inevitable, but with trifling hemorrhage and the cervix not dilated, it may be well to adopt an expectant course on the lines just referred to, although it would not be wise to leave the patient long at a time without a proper attendant prepared to tampon immediately if this is required, since at any moment hemorrhage may become alarming. If hemorrhage is severe or the patient is at some distance, without a trained nurse or other competent attendant, and the cervix not sufficiently dilated to allow an immediate delivery, the vagina should be thoroughly tamponed.

Every physician should carry a tampon in his obstetrical bag, ready for any emergency that may arise, but a kite tampon is quickly extemporized if the material is obtainable. It consists of about a dozen pieces of wadding, each the size of a small apple, attached to a string, each plug being about six inches from

its neighbor. Iodoform gauze also makes a good tampon, but is expensive.

Before inserting the tampon, the vagina should first be irrigated with a 1:4000 or 1:5000 bichloride solution; the patient is then placed upon her side in the Sims posture, the hip on the edge of the bed, the perineum well retracted with a speculum, and the vagina carefully and firmly packed with the tampon, which has first been well soaked in boro-glyceride. If the patient is weak or collapsed from hemorrhage, the tampon gives her time to pick up and opportunity for the attendant to administer stimulants and light nourishment; it is allowed to remain at least twenty-four hours, and in some cases has remained thirty-six or even forty-eight hours without becoming offensive. On removing the tampon the cervix is found dilated or dilatable.

If, when your patient is first seen, the cervix is fully dilated, with possibly the ovum presenting, or if the fetus has escaped and the abortion is incomplete, the whole or a portion of the placenta and chorion remaining, it is advisable to at once proceed to clean out the uterus. Conservative members of the profession usually adopt, even in these cases, expectant measures, unless excessive hemorrhage occurs or septicemia threatens, and trust to nature to rid itself of the offending contents, and doubtless the remnants of an abortion may remain in the uterus without any immediate danger. But so long as the ovum or any portion of the placenta, or any debris, remains in the uterus, hemorrhage may occur at any time, involution is delayed and septicemia may develop, if not in an acute form, in an insidious and none the less serious manner, resulting in endometritis, salpingitis, or other pelvic disease, rendering the patient a chronic invalid; indeed, there is no more fruitful cause of disease of the uterus and its appendages than neglected miscarriage.

In order to remove the contents of the uterus, the patient is placed with her hips well over the edge of the bed, or preferably she is lifted upon a table, and while the necessary manipulations are being carried on, the soiled clothes are removed, clean ones arranged, and the bed put in proper condition again to receive her. The lithotomy position is the best, the hips resting on a Kelly's pad.

The vagina and cervix are carefully disinfected before anything is introduced into the uterus. If the cervix is sufficiently dilated to allow of the easy introduction of one or two

fingers, an immediate effort is made to empty the uterus; if not, the cervix is dilated. This is very easily accomplished, and causes scarcely any pain. One or two sterile fingers are then introduced into the uterus for exploratory purposes, and any large mass that can easily be detached is removed. But, as a rule, the fingers cannot accomplish with the same ease and facility what can be done with the dull irrigating spoon curette. After the fingers have separated what they can easily, the curette is introduced, the entire uterus carefully gone over, and all the contents removed. If the uterus has been septic previously, a solution of 1:5000 bichloride is allowed to flow through the curette; otherwise sterilized water answers well. An anesthetic is not necessary.—*American Medico-Surgical Bulletin*, Sept. 12, 1896.

#### THE LIMITS OF NEPHRECTOMY.

P. WAGNER (*Chir. Beitr. Festschrift für Benno Schmidt*) warns against the too hasty removal of a kidney. Experience has shown that the remaining kidney in most cases does not undergo compensating hypertrophy, and cannot do the work of both organs, and that many patients finally die on account of insufficient renal action. "In no case," he says, "should a sound kidney be sacrificed, and an affected one only in case the lesion threatens the life of the patient. Those troubles which can ultimately be cured by conservative measures, even though long continued, are no excuse for nephrectomy, for even the smallest remaining portion of active kidney substance may be of vital importance."

Thus, in place of the various conditions which are held by some to justify removal of one kidney, Wagner advocates the following operations:

Nephrorrhaphy for floating kidney, including cases of intermittent hydronephrosis due to dislocation of the kidney.

Nephrolithotomy for renal calculi, whether in the kidney or its pelvis, in the absence of extensive suppuration or advanced alteration of the kidney substance.

Nephrotomy for pyonephrosis, hydronephrosis, and solitary cysts of the kidney or echinococcus cysts.

Partial resection for benign tumors, localized abscesses, calculus formation. This operation will probably have a much wider application in the future than it has at present.

Nephrectomy may be necessary either as a

primary or secondary operation. As a primary operation it is indicated for malignant tumors of the kidney or its capsule, in tuberculosis, and in abscesses which are distributed throughout the whole kidney; also in injuries which have badly lacerated the kidney and caused uncontrollable hemorrhage.

Secondary nephrectomy may become necessary in emaciated patients with suspected tuberculosis in other organs, whom nephrotomy and tamponade have failed to relieve. In cases of abscess in which the integrity of the other kidney is suspected, nephrotomy is first to be tried; this failing, the kidney should be removed. For a similar reason, badly lacerated kidneys whose artery and vein are intact, should be sewed, tamponed, or in part resected, and nephrectomy be performed only secondarily if these measures do not succeed.

There remain to be considered only pyonephrosis and hydronephrosis. Primary nephrectomy in these cases deprives the body of the use of some remnants of active renal tissue, whose loss under certain circumstances may mean great danger to the patient. Ayer's investigations have shown that a hydronephrosis almost never destroys all the secretory tissue. Nephrotomy in such cases can do no harm, and statistics show that the resulting fistulas usually close. In cases where a fistula has long continued to discharge urine or pus, a secondary nephrectomy is to be considered.—*American Medico-Surgical Bulletin*, Sept. 12, 1896.

#### SUBPHRENIC ABSCESS.

The difficulty of diagnosing this condition is well shown by the fact that in only two of the five cases observed by CARL BECK was a correct diagnosis made before operation. It is sometimes impossible to distinguish an encysted pyothorax from a subphrenic abscess. As regards exploratory measures: aseptic precautions having been observed, the needle should be introduced over the seat of abscess, and in case of a negative result reintroduced several times in different places—as the pus-cavity may be either of small extent, or it may contain a cheesy accumulation, or, finally, it may be divided into several minor cavities by adhesions; after each negative result a wire should be pushed through the needle, so that any pus which may have remained adherent to its inner surface may become detached. Occasionally it will be found useful to fill the syringe with sterile

water after the operation, and force the solution through the needle into a Petri dish. If the microscope does not give sufficient information, after examining this fluid, cultures may be made in properly prepared tubes.

The treatment of subphrenic abscess is practically the same as that of pyothorax. As a rule, the ninth or tenth rib, preferably in the median axillary line, is selected for resection. If the abscess be large, two or three ribs should be resected, in order that the whole cavity may be packed with gauze, which procedure seems to be the ideal treatment of any abscess. If the abscess be small, it will not generally be found within the axillary line; then the exploratory needle will always indicate the ultimate route of the incision. Exceptionally such abscesses may be reached below the costal arches or the xiphoid process.—*International Journal of Surgery*, October, 1896.

#### USE OF LARGE NON-PEDICULATED FLAPS FOR PLASTIC PURPOSES.

The fact that flaps of skin entirely separated from their surrounding tissues will heal if transplanted, has been known for more than a century. Skin-flaps taken from the thighs were used to make artificial noses in India during the latter part of the last century. Although these operations were performed by craftsmen, they were more successful than those done by the surgeons. The latter did not succeed in their efforts to utilize non-pediculated flaps until the middle of the present century, when Wolfe transplanted a flap to form an eyelid after having removed the subcutaneous fat. After the introduction and general adoption of the Thiersch method, this one was abandoned. KRAUSE was the first surgeon to successfully use flaps of skin extending down to the adipose layer. At first, following the method of the Indian craftsmen, he whipped the flap after having detached it upon three sides, in order to produce an artificial hyperemia; but this procedure appearing to be harmful, he abandoned it. The secret of success is most strict asepsis and the use of no antiseptic solutions or moist sponges—in other words, a perfectly dry operation. By baths, curettement, and wet aluminum acetate or creolin dressings, he prepares a granulating surface to which the transplantation is to be made, all cicatricial and chronically inflamed tissues being removed. Hemorrhage is checked by gauze sponges. The part of the body from

which the flaps are to be taken must be thoroughly cleansed, all antiseptic solutions being washed off with sterilized water. The flaps are cut off in the form of a longitudinal ellipse and are then shaped to the part to be covered. They are dissected up with a scalpel, cutting between the cutis and subcutaneous fat. After dissecting up the tip, this is folded in so that the wound surface of the flap is covered as more and more of it is freed. If a very small amount of adipose tissue remains, it will not interfere with the nourishment of the flap. The latter usually shrinks to two-thirds its original size longitudinally and a little less transversely. It adheres to the prepared surface as if glued on.

Secondary hemorrhage is most likely to occur when a flap is placed upon the cancellous portion of bone. It is better to wait a few days before transplanting upon such tissue, because nutrition of the flap through newly formed blood-vessels does not occur until the sixth day, and meantime the flap is nourished by diffusion from the vessels, which will be impossible if a blood-clot intervenes. Krause never transplants upon freshly severed tendons or upon cartilage, on account of the lack of sufficient nourishment for the flap.

In transplanting upon the leg or arm it is not necessary to suture the flap. The dressing must, however, be most carefully applied. The limb should be massaged daily after transplanting upon ulcers of the leg. In nineteen cases of such ulcers which Krause treated by transplantation, fifteen were successful after a lapse of three and a half years. He used this method in forty-seven cases, and was successful in the majority. The special indication for this method is the necessity for covering extensive defects upon the leg or arm, especially when a cicatrix is exposed to mechanical injury. The frequent ulceration of Thiersch's grafts under these circumstances renders them unfit for such surfaces.—*Volkmann's Sammlung Klinischer Vorträge*, No. 143, 1896.

#### A PAINFUL ADENOMYOMA OF THE ROUND LIGAMENT.

CULLEN (*Johns Hopkins Hospital Bulletin*, May and June, 1896) relates an important case in the practice of Dr. Kelly. The patient was married and thirty-seven years old. A swelling in the right inguinal region had been observed for eight years. Recently it became the seat of violent cutting pains,

which radiated to the back, and were most severe after exertion or at the menstrual period. When examined the tumor occupied the upper part of the right labium. An oval incision was made over it, and it was dissected from the round ligament; higher up on that process was a smaller nodule, about two-fifths of an inch long. The round ligament was cut off above the smaller growth, and its stump sutured in the canal, which was closed as in the radical cure for hernia. Recovery was rapid. The larger tumor was a firm nodule measuring over an inch and a third by one inch, and incorporated with a dense mass of subcutaneous fat: It consisted of unstriped muscular fibre, traversed in all directions by tubular bodies identical in appearance with uterine glands. Cullen insists that the excessive pain in the nodule at the menstrual period was significant, suggesting some definite sympathetic relation between the uterus and the nodule.

Leopold, Aschenborn, Coulson, Roustan and Martin relate cases of cystic myoma of the round ligament. The origin of the cysts is probably explained by Von Becklinghausen's recent discoveries.—*British Medical Journal*, Oct. 10, 1896.

#### IMMEDIATE CYSTORRHAPHY AFTER SUPRAPUBIC LITHOTOMY.

DE VIACCOS (*Rev. de Chir.*, August, 1896) holds that immediate suture of the opening in the bladder should, as a rule, be practiced after the high operation of lithotomy. Such practice, it is asserted, will very rarely be contra indicated by the state of the vesical coats. In 105 cases of suprapubic lithotomy observed by the author in his own practice and at different hospitals, there were only twelve in which the morbid changes in the bladder were so severe as to render useless the application of stitches. Complete occlusion of the vesical wound, it is acknowledged, cannot be attained by suture, however skilled the operator may be, nor by any method of stitching; but, the author argues, primary union of the wound does not depend on such complete occlusion—it is quite unnecessary to aim at this, provided every precaution be taken to prevent accumulation of urine in the bladder. An occlusion as complete as possible of the raw edges, and effectual catheterism, whether complete or intermittent, will suffice to guard the patient against any post-operative complication. The author recommends a continuous suture of catgut. The wound in the

bladder usually heals by the fourth or fifth day and before the catgut is absorbed. He has practiced, with good result, immediate suture after high lithotomy on old as well as on young patients, and is convinced that a perfectly sound bladder is not an indispensable condition for the success of this practice, nor is infancy a specially favorable period of life for it.

#### USE OF FORCEPS IN FRANCE AND GERMANY.

An article in the *Revue Internationale de Médecine et de Chirurgie* of August 10, 1896, compares the statistics of the use of the forceps in obstetric cases in France and Germany, greatly to the advantage of the French methods. The superiority of Tarnier's forceps (which are used in France) to Noegele's (which the Germans use) is one cause of the better results obtained. But the chief cause is the method of applying the forceps. In France the head of the fetus is seized symmetrically from ear to ear, the axis of the blades corresponding to the occipito-mental diameter, except in superior-strait cases. The practice in Germany is the reverse of this: the forceps are applied symmetrically to the axis of the pelvis, and the fetal head is seized as happens to be convenient. The statistics show the results in the frequent lacerations and elevated fetal mortality.—*Journal of the American Medical Association*, Sept. 19, 1896.

#### THE TOXIN TREATMENT OF MALIGNANT TUMORS.

In the *Wiener Medizinische Blätter* of August 27 we find an abstract of an account by MATAGNE, of Brussels, of his experience in the treatment of "inoperable" malignant tumors with Dr. Coley's erysipelas and *Bacillus prodigiosus* toxins, originally published in the *Gazette Médicale de Liège*. He has employed the treatment in fourteen cases, and maintains that in one of them a complete cure was accomplished. The patient was a man sixty-four years old, who in January, 1895, first noticed something abnormal in his mouth. In February he consulted a physician, who diagnosticated epithelium and advised an operation, to which the patient did not consent. Many other physicians saw the patient, and they all concurred as to the diagnosis and urged the man to have an operation performed. Early in June the patient consulted Dr. Matagne. By this time he had a three-lobed tumor which occupied

the floor of the mouth. The largest lobe was the size of a nut; in the left submaxillary region there was a gland as large as a small nut—the kind of nut is not specified in either instance—and under the chin there were two other glands the size of a bean. The tumor was hard and ulcerating, but without suppuration, and lancinating pains proceeded from it toward the left ear. In a short time the symptoms were so marked that no observer had a doubt of the epitheliomatous nature of the growth. However, no histological examination of the neoplasm was made, for fear of opening a channel for secondary infection.

The treatment was begun on the 10th of June. Five centigrammes of the toxin were injected beneath the skin of the neck below the hyoid bone. In two hours the man's temperature was 101.3°. On the 16th, forty centigrammes were injected into the tumor, and hard swellings made their appearance in half an hour; the tongue remained quite swollen for two entire days. The highest temperature reached during the treatment was 105.8°. During the whole febrile period the tumor diminished in size very decidedly, and the diminution kept on after the subsidence of the fever, so that by the beginning of September not a trace of the growth remained.

Another case was one of recurrent sarcoma of the neck in a woman seventy-eight years old. The tumor was as large as an egg and situated in front of the sterno-cleido-mastoid muscle. Another tumor, of the size of a hazelnut, was seated in the masseteric region, and two small but very hard glands were to be felt under the chin. After a course of treatment lasting three months and a half, the injections being given every second day, the large tumor had wholly disappeared and the one in the masseteric region could hardly be felt; but the enlarged glands had not undergone complete involution, when the treatment was accidentally interrupted. Six months later there was a moderate aggravation of the disease, and the patient was advised to submit to the injections again.

In a third case, one of recurrent sarcoma of the neck, of the size of a fetal head, treatment with the toxins was continued for three months, and the tumor had then shrunk to two-thirds of its original size. The patient, out of patience with the long duration of the treatment, decided to call in a surgeon, who operated, with a fatal result.

In a case of recurrent sarcoma of the arm the injections checked the growth of the

tumor only temporarily. In one of sarcoma of the pharynx no result was noted other than a brief restraint of the growth.

The sixth case was one of deeply ulcerated sarcoma of the neck in a very debilitated man sixty-four years old, who died during the reaction following an injection of ten cubic centimeters of the toxins after the treatment had been carried on for five weeks. The tumor had diminished in volume a little.

The other seven cases were all examples of epithelioma or carcinoma, and, except in two of them, the results were very slight. In one of these two, a recurrent carcinoma of the breast, the injections seemed to check the growth of the tumor, for it remained stationary for several months; in the other, a uterine carcinoma, there was alleviation of the pain together with reduction of the size of the tumor.

Such results as Matagne has reported certainly ought to encourage Dr. Coley to persevere in his labors. It is evident, we think, that the toxin treatment is of some value, more particularly in cases of sarcoma; the problem is, to ascertain the class of cases in which it holds out a distinct promise of proving decidedly palliative if not curative.—*New York Medical Journal*, Sept. 19, 1896.

#### PLASTIC SURGERY.

The *Journal des Sciences Médicales de Lille* of August 15, 1896, describes a case where a cutaneous epithelioma on the ankle, twelve by nine centimeters, was removed, a pear-shaped living flap from the thigh sutured in its place, and the leg flexed against the thigh in a plaster cast. A small flap cut above was twisted around to cover the centre of the open space, leaving only a couple of unimportant spaces at each end uncovered.—*Journal of the American Medical Association*, Sept. 19, 1896.

#### POST-OPERATIVE INTESTINAL OBSTRUCTION.

ADENOT (*Revue de Chirurgie*, January, 1896) divides post-operative intestinal obstruction into the following classes:

1. Occlusion caused by adherence of the intestine to raw surfaces, intraperitoneal drains, and inflamed organs.
2. Occlusions due to bands.
3. Those due to anomalous position of the intestines.
4. Those due to an exaggeration of the normal left subcostal angle of the colon.

5. Spasmodic occlusion.

6. Occlusion due to inefficient operative procedures.

There are three marked symptoms of post-operative intestinal obstruction, viz.:

1. Persistent absence of the passage of flatus.

2. Nausea and vomiting.

3. Painful point in abdomen.

As regards treatment, one should not delay too long. While it is legitimate to try mild purgation, insertion of rectal tube, etc., the continuance of such treatment should be abridged proportionally to the severity of the symptoms and clearness of diagnosis.

The abdomen should be opened largely. Work quickly and have good assistants. Examine the cecum; if it is not distended, the occlusion is located higher up in the small intestine; if it is distended, explore the sigmoid flexure. One should always follow a definite plan: first ascertain the extent of the occlusion, then its location, and, lastly, the cause. Examine the pedicles, raw surfaces, angles of the intestine, drainage apparatus, etc. Examine the colic flexure of the left side. If the obstacle cannot be found, evisceration must be performed. Recourse should not be had to this grave procedure too readily, notwithstanding that it has succeeded in the hands of Jaboulay and Pollosson. Tuju seems to resort to it rather steadily. Sometimes an artificial anus is necessary, but it is not an operation of choice.—*University Medical Magazine*, October, 1896.

#### STRAIGHTENING THE SPINE BY WIRING THE SPINOUS PROCESSES TOGETHER.

CHIPAULT's new method of treating caries of the spine is described in the *Therapeutische Wochenschrift*, 1896, No. 35. The spine is straightened, and held in this position by wires that fasten the spinous processes together, so that the orthopedic appliances do not have to contend with a constant tendency to curvature. After chloroform, the patient is placed on his belly, three-quarters pronation, the back turned to the operator. A longitudinal opening is then made along the spinous processes, two to three vertebrae above and below the limits of the curvature. Without touching the interspinous ligaments, both sides of the processes are exposed and the soft parts drawn aside; the assistant at each end then pulls the spine to straighten it as much as possible, and a silver wire is

passed through the interspinous ligament above the highest process to be ligated, at the bottom, near the root. The wire is then cut, leaving on each side a piece twice as long as the wound. The ligating is done with these two ends, crossing them back and forth and passing them through each interspinous ligament from the highest process downward until the lowest is reached, when the two crossed ends are twisted together. The wires must be passed through the ligaments close to the lower edge of the process above, to afford as firm a support as possible. Each crossing must be tested to see if it is strong and taut before proceeding to the next. The soft parts are then sutured without drainage, the wound bandaged, and the patient placed in bed. The two difficulties—lateral curvature of the spine, and ankylosis of adjoining processes—are met by boring a hole in the processes in the latter case, and in the former by extending the end of the wire on the convex side up to the loop at the top and stretching it tight, which straightens also the lateral curve. In cases of lumbar or dorsal caries, the bandage can be changed in five to six days, and in cervical caries in ten days, the stitches being then removed from the soft parts.

This ligature of the spinous processes is undoubtedly an advance in the treatment of Pott's disease, but it only applies to moderate curvatures of recent origin that have commenced suddenly and developed rapidly and are capable of reduction in anesthesia, and to weak spines. It is not adapted to old curvatures or those involving too many of the vertebræ. The presence of an unopened cold abscess or of paralysis is not an obstacle. Absolute immobilization should follow the operation.—*Journal of the American Medical Association*, Oct. 3, 1896.

#### PATHOLOGICAL CONDITIONS OF THE PELVIS.

Dr. H. T. HANKS (*American Gynecological Journal*, July, 1896) writes as follows with regard to the choice of operation in this class of cases:

If the surgeon is well equipped, he should do a vaginal operation—a vaginal hysterectomy, in fact—when practicable:

1. For a suppurative pelvic disease, if located in the true pelvis, when exudation covers and agglutinates the uterus, tubes, ovaries, and rectum.

2. For ovarian abscesses.

3. For an unruptured tubal pregnancy, and for a ruptured tubal pregnancy in the broad ligament.

4. For small ovarian and parovarian movable cysts, and other small movable tumors.

5. For movable uteri, with small fibroids.

6. For carcinoma uteri when the uterus only is involved.

#### TREATMENT OF DETACHMENT OF THE RETINA.

CASEY A. WOOD, in the *Journal of the American Medical Association* of October 3, 1896, speaking of treatment in this condition, says detachment of the retina does not occur often in this country, but he has on his records six cases that consented to be treated for a sufficient length of time to make his experience with them worth mentioning. The treatment for two was scleral punctures, for one iridectomy, and the other three had prescribed for them continued rest in bed with pilocarpine injection. Only in one case, treated by puncture and pilocarpine, was there a field expanded, and the central vision improved to finger-counting at seven feet, although at one time it was reduced to perception of light. This improvement continued for nearly a year, when the patient was lost sight of.

Wood's experience leads him to think, with Bull of New York, that we have as yet discovered no better device than that resorted to with occasional success by the older ophthalmologists, viz.: rest in bed, bandages, atropine, and the internal use of some absorbent. Instead of the long-continued use of pilocarpine, especially when that drug is ill-borne by the patient, we may substitute soda bicarbonate and potassic iodide, well diluted with water. In all recent cases where the eye is quiet and there is no vitreous strand to sever, conjunctival puncture of the sclera may do temporary good and vision be improved. Division of fixed membranous bands in the vitreous may be done without causing much reaction, and may prevent extension of the disease. He does not approve Scholer's method.

Many cases of spontaneous cure are recorded; indeed, one may safely say that of all the histories of cures, temporary and permanent, at least ten per cent. were accomplished without treatment. So numerous and well authenticated are these recoveries that a large percentage of the results obtained after iridectomy, removal of the lens, the

use of atropine, bandaging, pilocarpine, etc., and even in some cases after posterior operation, are really brought about by local rest—by putting the patients in such a position that they cannot by over-exertion of any kind make a bad matter worse. The retina, having meantime broken loose from its connection with the shrinking vitreous, returns to its natural position—and the treatment, medical or surgical, receives the credit.

#### THE SUTURING OF ARTERIAL WOUNDS.

HEIDENHAIN (*Centralbl. für Chir.*, 1895, No. 49) reports a case in which, during removal of a carcinoma of the breast, the axillary artery was wounded. The edges of the wound were caught with hemostatic forceps, and a continuous suture of catgut introduced with needles such as are used in inserting intestinal sutures. The wound was packed, and not closed until the end of forty-eight hours, when all danger of secondary hemorrhage seemed to be passed. The case recovered completely, and there was no evidence of a traumatic aneurism when the author examined the patient six months later. The author advises the use of catgut, such as is used for ligatures, and the union of endothelium to endothelium; sometimes there is a slight oozing through the stitch-wounds after the suture is completed, but packing for a few minutes will stop it. He does not believe it is necessary to heal the wound by secondary suture, as the healing of the tissue about the artery tends to support it.—*American Journal of the Medical Sciences*, December, 1896.

#### ROENTGEN RAYS IN GUNSHOT WOUNDS OF THE HEAD.

MAX SCHEIER (*Deutsche Med. Woch.*, Oct. 1, 1896) relates a case where by means of the Roentgen rays it was possible to prove the presence of a bullet in the brain and approximately to localize its position. A man, aged twenty-seven, received a gunshot wound five years ago, just above the outer end of the superciliary ridge on the right side, followed by unconsciousness. No exit wound was to be found. Later, amaurosis in the right eye, swelling and prominence of the eyeball, and dilatation and immobility of the pupil, were observed. The right face was anesthetic. The bullet was thought to be present in the orbit, where a large blood-effusion had taken place. The bullet could not be found there, but the inner and upper part of the orbital

wall was ascertained to be splintered. Five years later there was complete paralysis of the right fifth nerve except its motor branch, and paralysis of the olfactory and optic nerves. Buka took a Roentgen photograph of the head. A shadow five millimeters in diameter, eighteen millimeters from the root of the nose and eight centimeters from the back of the skull, was distinctly seen. The position of the bullet was somewhere in the neighborhood of the right Gasserian ganglion. If a photograph could have been taken immediately after the injury, the exploration of the orbit would have been found to be unnecessary. A fracture of the base of the skull must have occurred, and thus the paralysis of the optic and olfactory nerves was brought about. Perhaps an operation undertaken immediately after the accident might have relieved the pressure on the trigeminal nerve, and thus prevented the paralysis.

#### THE COURSE AND PROGNOSIS OF ORBITAL TUMORS, AS INFLUENCED BY SURGICAL OPERATIONS FOR THEIR REMOVAL.

The following conclusions are based upon the histories of thirty-six cases, all taken from the private practice of Dr. W. T. BULL (*New York Medical Journal*, Aug. 29, 1896), as it has been proved that patients in private practice can be more satisfactorily followed up than those in hospital practice. All these cases have been watched from start to finish by the writer, and the course of the disease and the results of operative interference are given in detail in his paper. In a much larger experience, extending over a period of twenty-five years of hospital service, the same conclusions have been forced upon him.

1. The prognosis of all forms of malignant orbital tumors, whether primary or secondary, is unfavorable; and if the tumor is primarily in one or more of the deep facial bones or their sinuses, the prognosis is positively bad.

2. Except in the case of encapsulated tumors of the orbit, surgical interference is almost invariably followed by a return of the tumor; and the growth of the secondary tumor is more rapid than that of the primary lesion. With each succeeding operation the period of quiescence in the return of the tumor grows shorter, and the rapidity of the growth increases.

3. The patient's family, and in certain

cases the patient himself, should in the beginning be told of the serious nature of the trouble, and be warned that complete removal of all disease germs is a well-nigh hopeless task. The burden of the decision as to surgical interference must rest upon the shoulders of the patient.

4. Repeated operations in these cases undoubtedly shorten the life of the patient. While it is, therefore, our duty to operate in all cases in order to relieve severe or unbearable pain, we should be slow to operate merely for the sake of relieving temporarily physical disfigurement or deformity, especially if we are convinced that by so doing we shorten the life of the patient, even if that shortened life is rendered more bearable to him.

#### LITHIASIS IN BOYS.

SCHWEIGER (*Wiener Med. Woch.*, Sept. 12, 1896) states that in Hungary children suffer not infrequently from stone. He reports ten cases, the ages of the patients varying from two and a half to twelve years. In the matter of treatment he strongly advocates, for private practice, suprapubic cystotomy, which, he states, requires no unusual instruments and no special skill; in these respects it stands to lithotomy as does tracheotomy to intubation. He finds the suprapubic operation very easy in children, and even safer than litholapaxy, though the time in bed is somewhat longer. The bladder, which heals very readily in young subjects, should be at once sutured completely with silk, no drainage being adopted. The only special source of difficulty is the great reflex excitability of the bladder in children, which may prevent its being properly distended; a low insertion of the peritoneum may also complicate the operation. The author has had no trouble with the stitches in any case; he does not think they should ever require removal. Stones are sometimes impacted in the urethra, whence the simplest mode of dislodgment is a prolonged warm bath, which is often effective alone. In one of the author's cases a periurethral abscess had formed, which, when cut down upon, was found to contain the stone; in another the concretion was removed by urethrotomy, and in a third it was extracted from the cavernous urethra by suprapubic cystotomy. In both the latter cases retention and dribbling had persisted for some days, and the bladder reached nearly up to the umbilicus.—*British Medical Journal*, Oct. 31, 1896.

#### CICATRICAL STENOSIS OF LARYNX; INTRALARYNGEAL DIVISION AND INTUBATION.

In the *Birmingham Medical Review* for June, 1896, Mr. F. MARSH reports the case of a girl, aged five years, who had tracheotomy performed for membranous laryngitis. Various unsuccessful attempts were made for twelve months to dispense with the tube. Under chloroform a laryngoscopic examination was made; considerable cicatricial stenosis, somewhat cone-shaped, was found in the upper part of the larynx, and a small probe only could be passed through into the trachea. The cicatrix was divided with Heryng's intralaryngeal knife, and a second largest size O'Dwyer's intubation tube introduced, the smaller sizes being expelled (probably owing to the shape of the opening); the tracheotomy tube was then removed, and the wound healed rapidly. Nineteen days later the intubation tube was removed, but, as asphyxia was threatened, the largest size O'Dwyer's tube was inserted. It was intended to remove this in a fortnight, and then, if it could not be dispensed with, to do a thyrotomy and excise the cicatricial bands. However, an attack of typhoid fever developed, and the tube was allowed to remain *in situ* for two months, when it was removed without any embarrassment to respiration. The voice was improving when the case was reported.—*Intercolonial Medical Journal of Australia*, July 20, 1896.

#### THE OPERATIVE TREATMENT OF VARI- COSE VEINS, WITH ESPECIAL REF- ERENCE TO A MODIFICATION OF TRENDELENBERG'S OPERATION.

MOORE (*Intercolonial Medical Journal of Australia*, July 20, 1896) sets forth a method of his which differs from that practiced by Trendelenberg, in:

(a) The site of the ligature. As the operation aims at preventing any reflux of blood into the vena saphena and its branches, this object is surely much better attained by ligating above the junction of any of the branches belonging to the lower extremity; if the ligature is applied low in the thigh, this object is not attained with the same certainty. Further, there appears to be no objection, theoretical or practical, to placing the ligature near the groin.

(b) The direction of the incision. The almost transverse direction of the incision

follows as a matter of course the adoption of the high site of ligature, for near the groin the lines of cleavage of the skin run almost transversely. The edges of this incision come into apposition much more readily than do those of a longitudinal incision. The vein also is more easily found through an incision running directly across it.

(c) The ligature material. Silk would seem to be much more suitable than any animal ligature. Only a fine thread is required, and it can easily and certainly be rendered aseptic. When silk is used, it is not necessary to tie two ligatures and divide the vein, though this practice should be adopted as a rule. Being more certainly made aseptic, and less liable to give way, silk is much the more suitable material in out-patient practice, where the patients are allowed to go home and are thus out of reach.

(d) The dressing. Boric powder with a little absorbent wool, kept in place by colloidion, forms a very comfortable, dry, aseptic dressing, much better than any bandage.

(e) Allowing the patient to go home. This proceeding the writer scarcely cares to advocate, though he is quite prepared to defend it. If there were unlimited beds, then such cases might no doubt be treated as in-patients, with less anxiety to the surgeon.

The fifteen cases treated in the out-patient department have done as well as could be desired, and the operation certainly enlarges the province of the out-patient surgeon.

#### PERINEAL PROSTATECTOMY.

E. NEINHAUS (clinic of Socin, Basel), after a very thorough review of the different methods of treating enlargement of the prostate, all of which have proven more or less unsatisfactory, presents the histories of eleven cases of perineal prostatectomy performed by Socin, Schede, and Küster. Schede and Küster operated by Von Dittel's method, which consists in removing more or less of the prostate through an incision starting from the coccyx, extending along the median line to the anus, then turning to the right of the anus by a semicircular incision and terminating in the perineal raphe in front of the anus. The rectum is torn away from the prostate, and the field of operation is brought well into view. The wound is treated by the open method.

Socin modified the operation in that his incision began at the tuberosity of the ischium on one side, extended forward in a curved line to the bulb of the urethra, then

backward and outward to the tuberosity of the ischium on opposite side (the transverse curved incision of Kocher). This incision exposed the whole of the prostate and allowed the rectum and urethra to be well drawn out of the way.

None of the eleven patients operated upon died of the operation. Two died of carcinoma which was not diagnosed at the time of the operation, and one died of hemorrhage and sepsis two years after.

Spontaneous micturition returned in every case, and continued in all but one. Only six of the cases can be considered as cured, since the remainder have been troubled with persistent fistula due to accidental injury to the urethra or rectum.

On the whole the results of lateral prostatectomy have not been very brilliant, but it must be remembered that the operation has been undertaken in only the worst cases. The statistics will undoubtedly improve when the operation is performed on more favorable cases. It is indicated in cases in which there is retention of urine from general enlargement of the gland or enlargement of one or both of the lateral lobes. An enlarged or pedunculated middle lobe can best be removed by suprapubic cystotomy.

In order to be successful the operation must be undertaken before the mucous membrane of the bladder is affected with important catarrhal changes, and before the tone of the muscle is entirely lost; otherwise the bladder will not be able to expel the urine after the obstruction to its discharge has been removed.

Mention is made of the numerous cases treated successfully by castration: the author thinks there is no doubt about the efficacy of this method in some cases, but brings up the question whether all forms of prostatic hypertrophy can be influenced thereby; *a priori* it seems very doubtful.—*Beiträge zur Klinische Chirurgie*, band xiv, heft 2; *Annals of Surgery*, December, 1896.

#### SURGICAL TREATMENT OF SPASMODIC TORTICOLLIS BY KOCHER'S METHOD.

QUERVAIN (*La Semaine Médicale*, 1896, No. 51), as the result of a statistical study, finds that operations on the spinal accessory nerve designed to cure spasmodic torticollis are mostly abortive. Among sixty-one collected cases, including ligature, stretching, avulsion, and resection, there were only twelve cures; twenty-two cases were improved. Kocher,

discouraged by the results of seven operations on the accessory nerve, has adopted a method of his own since 1884. This consists of complete cross-section of all the involved muscles. The results are far better than those reported from any other method. In all, twelve cases were treated. Each of these had been subject to a thorough, prolonged and persistent palliative treatment, including medicaments, massage, hydrotherapy, electricity, and orthopedic appliances. This cross-section of the muscles did not cause atrophy and paralysis, nor did it materially interfere with the mobility of the head. Of the twelve cases operated on, seven were definitely cured; the remaining five are still under a prolonged manipulative and gymnastic treatment which Kocher considers absolutely essential after his operation.

The somewhat naive explanation given as to the rationale of the cure is that the nerve-centre (irritation of which is undoubtedly the cause of torticollis in the great majority of cases), on sending out its impulse to the muscles, is so discouraged at the lack of result that it ceases to trouble in this way.

#### THE ANTISEPTIC VALUE OF IODOFORM IN SURGERY.

LOMRY (*Archiv für Klin. Chir.*, bd. liii, heft 4) says:

If wounds inflicted on dogs or guinea-pigs are infected with staphylococci or streptococci and are treated with iodoform, they heal more quickly and secrete less than those which are not thus treated. Iodoform lessens the virulence of these micro-organisms; neutralizes or destroys the microbe toxins, but not completely; it does not lessen the ameboid motion or the phagocytosis of the white blood-corpuscles.

[This seems faint praise for a drug which is so foul to the smell and so extremely poisonous.—ED.]

#### PLUGGING OF BONE-CAVITIES WITH ANTISEPTIC SUBSTANCES.

ISCH-WALL and REYNIER state that salol, which is soluble at 40°C., may be melted and poured into bony cavities, where it moulds itself accurately to the space requiring filling and becomes practically vitreous in consistence. Liquid salol possesses the advantage of dissolving iodoform. Thus can be formed an excellent mastic with which to plug small

osseous cavities that have been carefully cleansed and disinfected. The authors state that they have employed this method in thirty cases, with excellent results except where, because of the depth of the lesions, the cleaning out of the bone was not thorough.

#### A METHOD WHEREBY RUSTING OF INSTRUMENTS DURING STERILIZATION IS PREVENTED.

LEVAI (*Wiener Klin. Rundschau*, 1896, No. 31), after an experimental investigation as to the rusting of instruments, finds that the process is due to carbonic acid contained in water, and that it is not absolutely prevented by the addition of carbonate of soda, as recommended by Schimmelbusch. He states that rusting can be greatly lessened by first boiling the water before placing instruments in it, since thus the greater part of the carbonic acid is expelled. The most efficient means he finds is to add to the boiled water 0.25 per cent. of sodium hydrate, pure, containing no sulphur. During the operation the instrument should lie in the solution thus prepared. Sharp knives placed in this solution do not lose their edge in the faintest degree.

#### THE TREATMENT OF EXTRA-UTERINE PREGNANCY, RUPTURED IN THE EARLY MONTHS, BY VAGINAL PUNCTURE AND DRAINAGE.

The above is the title of a valuable contribution to this subject by KELLY, of Johns Hopkins (*American Gynecological and Obstetrical Journal*, August, 1896).

Cases suitable for Kelly's mode of treatment are the extra-uterine pregnancies which rupture in the early months, including therefore the vast majority of all cases. Since he has begun to follow this mode of treatment, all the cases which have come to him have been of this class.

Vaginal puncture and drainage is not a suitable plan of treatment in an unruptured extra-uterine pregnancy, in a recently ruptured one, or in advanced extra-uterine pregnancy.

Kelly's operation is not to be compared with the removal per vaginam of the dead fetus presenting at the vaginal vault (elytrotomy) in an advanced pregnancy, followed by drainage of the sac, nor is it to be compared with cases in which suppuration of the sac has occurred, which belong rather to the pelvic abscesses, although both classes of

cases he treats in precisely the same way. These cases are referred to by Hermann, who states that when the effusion of blood is followed by pyrexia the indications for excision of the vagina are the same as those in hematocele from any other cause, but when interference is called for to arrest hemorrhage soon after rupture has taken place, abdominal section is more likely to succeed than vaginal.

The class of cases to which the writer refers are not clearly defined by Hermann, and are the commonest of all; they are those in which a succession of ruptures has occurred, each time adding to the accumulation of clots in the abdomen. He has only included in his list one suppurative case with clots, and that simply for the purpose of reporting all the cases he has had.

In the *American Gynecological and Obstetrical Journal* (May, 1896), Dr. G. W. Reynolds reports a case of extra-uterine pregnancy which he felt certain had ruptured into the broad ligament, and in which he removed a three months' fetus with placenta and cord by a vaginal incision. A gauze drain was inserted, and the patient rapidly recovered.

Kelly pursues the following method in performing this operation:

1. After a careful consideration of the history, a thorough bimanual examination of the extra-uterine sac is made, both per vaginam and per rectum, in order to determine its exact relationship to the vaginal vault.

2. The patient is then put into the lithotomy position, and the vagina thoroughly cleansed.

3. The posterior lip of the cervix is caught with tenaculum forceps and drawn forward.

4. With the index finger resting on the prominent part of the sac posterior to the cervix to act as a guide, a pair of sharp-pointed scissors is thrust through the septum into the sac, taking care to follow the line of the axis of the pelvis. If this precaution is not taken, there is risk of puncturing the rectum by carrying the points too far back. If the rectum lies near to the vaginal vault, it is best to protect it from injury by the middle finger resting on the sac in the bowel and the index finger on the vaginal vault, thus straddling the perineum. If the sac does not lie so close to the vaginal vault as to be easily felt there, it may often be brought into relationship with it by the pressure of an assistant's hand above, when the puncture may be made.

5. When the scissors have entered the sac,

they are spread and withdrawn wide open. This makes the hole larger. A uterine dilator is then introduced, and the opening stretched to 1.3 to 3.5 centimeters in diameter.

6. As soon as the scissors are spread, a little stream of dark telltale blood runs down the vagina, confirming the diagnosis. After dilating the opening, the sac is emptied of blood-clots, placenta, and fetus, by the index and middle fingers. This is done with extreme care, using the fingers within the sac, and assisting their action by the other hand employed outside to make counter-pressure through the abdominal wall. In this way the sac is freely handled, its various parts kept within reach, clots are detached, and the contents removed until nothing but a shell remains—all without opening the peritoneal cavity.

Should the peritoneum be opened accidentally, no harm will result if the sac is well cleaned out and efficient drainage used.

If the fingers possess a good tactile sense, the rough limiting walls of the sac and the adhering clots will be easily differentiated. I have several times recognized the firm, round tube-casts, and brought them out broken up; the rounded sides of the pieces showed plainly that they had formed part of a cylinder.

7. If the cylinder is well closed off from the peritoneum, it is a help in bringing away the blood-clots to wash it out at intervals with a normal salt solution; I do this also at the end of the cleansing process, before packing.

8. The sac is then drained by a strip of plain or washed iodoform gauze, about three centimeters wide, stuffed loosely into its cavity with a packer. The gauze must fit loosely, so as not to stop the outward flow.

9. The gauze is left in for three or four days, during which time there may be a free serous flow. Then day by day it is withdrawn, and in from five to seven days removed altogether. The sac is daily washed out with a boric-acid solution, putting a piece of gauze into the opening each time to keep it from closing too fast.

In this way the sac contracts and closes in from two to six weeks, often without any evident suppuration, and in all cases without any marked purulent discharge.

In four cases out of the thirteen the writer opened the abdomen before evacuating and draining the sac—by the vagina in three of them, and above Poupart's ligament in one. He did this in the first two instances expecting

to enucleate the mass by way of the abdomen, but, finding that this would greatly endanger the patient's life, he turned to the vaginal route. With his present established technique he finds it but rarely necessary to open the abdomen. He did this, however, in one of his most recent cases because the history of rupture was so negative, and the encysted mass of blood at the left uterine cornu formed such a well defined tumor, that he felt doubtful whether it might not be an unruptured extra-uterine pregnancy. On opening the abdomen and finding the sac well covered in by sigmoid, rectal, and vesical adhesions, he evacuated it per vaginam, and drained it as usual.

The one great advantage of this operation is that, in accordance with the most recent and best gynecological practice, none of the pelvic structures are removed while the hemorrhage is opened, evacuated, and drained. All Kelly's patients have recovered perfect health, and there have been no untoward sequelæ.

A further advantage of great importance is the fact that a serious abdominal operation is often avoided, and the adhesions walling the sac in are let alone, while the sac itself is simply, quickly, and safely opened by way of the vagina.

In several of his cases the patients were in such condition that they could not have survived any prolonged abdominal operation. The vaginal operation in this way reduces the mortality.

The dangers of the operation are (a) the possibility of a mistaken diagnosis, (b) the risk of opening the peritoneum, and (c) the risk of a fatal hemorrhage, as well as (d) the liability to sepsis through the open vaginal vault.

Although the author made a correct diagnosis of extra-uterine pregnancy in each of the thirteen cases here reported, he diagnosed this condition in two cases where it did not exist. One was a dermoid cyst about as big as the fist, which was punctured, evacuated, and removed; and the other was a pelvic abscess, which was also opened and drained. Both cases recovered.

Hemorrhage is the most serious risk incurred, and the query naturally arises why it does not more frequently follow the opening of the sac, the detachment of the clots, and the relief of the pressure they afford the sac-walls. The answer to this must be that the vessels are filled with firm thrombi, and all tendency to active bleeding is past.

In the history of one patient who bled persistently from the vaginal puncture, necessitating the immediate removal of the sac by the abdomen, there was nothing to indicate anything different from the five preceding or the six following cases. She was forty-one years old, the mother of six children, the youngest two and a half years old. About three months before she was seen, at a menstrual period she was suddenly seized with a sharp pain in the lower abdomen, and became very faint, without losing consciousness. There was a mere "show" at the time, but after the pain she had a free bloody discharge for four weeks. The abdomen was enlarged and tender, and she had three attacks after the first, and was compelled to go to bed each time. The writer found her greatly debilitated and anemic, with constipation, and a pulse of 100. A large globular mass filled both sides of the pelvis, being especially prominent on the right side. The sac was punctured by way of the vagina, and the clotted blood and a three-months' fetus removed. This was followed by a free discharge of bright arterial blood, which oozed persistently out of the incision, and could not be controlled by packing. The abdomen was at once opened. The tubes and ovaries were so closely matted together with the uterus, that they were removed by hysterо-salpingo-oöphorectomy, bringing up the ectopic sac with its placenta. Seven hundred cubic centimeters of salt solution were infused into the cellular tissue to make up the loss of volume in the circulation. The patient was discharged on the twenty-ninth day, completely recovered.

On account of the possibility of this accident, the writer insists that the operator should always be prepared to open the abdomen if necessary when he undertakes to evacuate the sac by a vaginal opening.

## Reviews.

---

TWENTIETH-CENTURY PRACTICE OF MEDICINE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M. D. In Twenty Volumes. Volume VII: Diseases of the Respiratory Organs, the Blood, and Functional Sexual Disorders.

New York: William Wood & Co., 1896.

As our readers are already aware, from the review in a recent number of the THERAPEUTIC GAZETTE, Volume VIII of the Twentieth Century Practice of Medicine appeared be-

fore Volume VII, which is now under review, owing to the fact that certain delays which could not be avoided prevented the prompt appearance of the volumes in their regular order.

Because of the contents of this volume, we have looked forward to its publication with very considerable interest, for, while some of the subjects are well worn and are pretty thoroughly understood by the profession in general, others have advanced through research with such great strides that an author has ample opportunity of making what may be considered almost an original contribution to medical literature by giving a good summary of our present knowledge. We preface what we are going to say in regard to the individual articles by stating that we can repeat all the words of praise for this volume which we have given to its predecessors; indeed, we think that in some respects it surpasses most of the earlier volumes. That the editor has had some difficulty in obtaining from his various contributors their manuscripts with the promptness which was desirable, is evident from the classification and arrangement which he has been forced to adopt. Thus, the classification in one volume of diseases of the respiratory organs, of the blood, and the functional sexual disorders, is one which, of course, is not justified by any plan based upon scientific medicine.

The first article in Volume VII, upon Diseases of the Pleura, is written by Dr. Whitney, of Denver, and includes a consideration not only of these pathological states, but also of their various associated conditions and sequelæ. It extends, with its bibliography, over 126 pages, and is a good summing up of our knowledge concerning the topics of which it treats, although in one or two instances some of the recent literature upon this subject has apparently been overlooked: very little attention is given, for example, to the condition of pulsating pleurisy.

The article upon Asthma, which covers fifty-three pages, is by Franz Riegel, of Giesen, and is very German in its characteristics. It contains nothing new, that we have been able to find, in regard to the etiology, pathology, or treatment of this troublesome affection. A good illustration of Cürschmann's spirals may be found upon page 147.

The next article, that upon Diseases of the Mediastinum, by E. Main of Paris, is by long odds the poorest of any that we have seen contributed to the eight volumes so far issued. Not only does it only cover seven and a half

pages—which perhaps is not too little—but it shows no evidence of examination of any literature upon this subject, while much of the therapeutics which are advised will prove perfectly futile in the conditions for which treatment is recommended. It seems to us that this article could have been left out of the volume with advantage.

The next article, however, is one which amply compensates for any fault which can be found in its predecessor. It is by Dr. Alfred Stengel, upon Diseases of the Blood. In the discussion of his subject Dr. Stengel contributes no less than 290 printed pages, and therefore his article is a very large part of the volume. After a careful examination of it we find that it demonstrates: first, that its author has a thorough acquaintance with the modern literature concerning the blood; and, second, that he has had ample practical experience in the examination of this important liquid. Some of the illustrations must be considered unusually good, particularly when we take into consideration the fact that none of them are colored. Stengel's article will not only bring a great deal of credit to its author, but will do much in aiding in the sale of this valuable series.

Drs. Cushing and Cumston contribute the article upon the Disorders of Menstruation. We find nothing particularly noteworthy in this article, save that it is provided with a sufficient number of prescriptions to show that the authors are writing for practicing physicians who often desire formulas for the administration of remedies recommended in the text.

The article upon Functional Disorders of the Male Sexual Organs, by Dr. Allen, is a fairly good one and presents the subject quite exhaustively.

The last article in the volume, which covers 120 pages and of which no mention is made on the title page, is upon the Chemical and Microscopical Examination of the Urine, a subject certainly not in any way connected with the other subjects we have named. It is, however, a good summary of the literature of urine-examination, though it covers little ground that is not gone over in most of the good manuals devoted to the subject.

A REFERENCE BOOK OF PRACTICAL THERAPEUTICS.  
By Various Authors. Edited by Frank P. Foster, M.D.  
In two volumes. Volume I.

New York: D. Appleton & Co., 1896.

We are told in the preface of this volume that the editor's leading idea has been to

make the matter which it contains pre-eminently serviceable to the practicing physician, and that for this reason only so much of the mineralogical, chemical, botanical and historical relations of the various drugs have been given as are absolutely necessary for the thorough understanding of the uses of each remedy. We are also informed that the book is not intended to take the place of treatises upon materia medica and therapeutics, but has been published for the purpose of supplying the practicing physician with a summary of the therapeutic facts which have been gathered together during the last few years. These facts, it is believed, are many of them valuable, and yet are so scattered as not to be readily available to the average practitioner. With this opinion, however, we cannot coincide, for almost every one of the ordinary text-books on therapeutics which has reached advanced editions contains very accurate information concerning the latest therapeutic advances. The editor has also thought it wise to include very little information concerning the physiological action of the remedies which are considered.

The text of the volume is printed in double columns, and the subjects are arranged alphabetically, the present volume extending from A to M. No index is published in this volume, but we are told that an index of remedies and diseases will be published in the second or final volume.

It will be seen, therefore, that this book may be considered as the first volume of an Encyclopedic Therapeutic Dictionary.

Of the thirty-three contributors, sixteen are from New York, the remainder consisting of one representative each from San Francisco, Baltimore, Buffalo, Washington, Cincinnati, and other cities. There are two writers from Philadelphia, Dr. S. Solis Cohen and Dr. Burchard, the latter writing upon subjects connected with dentistry.

We have looked over the book pretty thoroughly and find that the editors have left out but little that is of value. In some places, it is true, the writers have been satisfied to gather their information from abstracts published in the columns of various journals, and have not consulted the original articles themselves. The result of this is that there are some inaccuracies in quotation and in statement. Again, we notice that in one or two instances the names of journals that are mentioned by way of reference are given a wrong title. Thus, on page 84 the experiments of Chantemesse and Widai are cred-

ited to the *New York Therapeutic Gazette*, a publication which does not exist. We presume the *New York Therapeutic Review* was intended. Further, the quotation is from an abstract and not from the original article. If we are not much mistaken too, the name of Widai is wrongly spelled in the text, which would not have been the case had the original article been consulted. Again in connection with the serum-therapy of syphilis, we notice that the name of Feulard is spelled Fenlard.

We also think it is a mistake to include in a book of this character combinations of various medicinal substances which are proprietary and sold under copyright or trademarks, as is done in a number of places in the volume.

Aside from these irregularities, there are one or two errors in regard to therapeutics and the physiological action of drugs, to which we think attention may justly be called. Thus, the statement on page 341 that death from digitalis poisoning results from cessation of the heart's action in systole caused by exhaustion of the motor ganglia or by the tetanizing effect upon the cardiac muscle, is certainly incorrect for the heart of a mammal. Further, we do not believe that exhaustion of the motor ganglia of the heart would result in systolic spasm of that organ. In man and the higher animals the condition of the heart after death from digitalis poisoning is that of diastole.

Again, we do not believe the profession will endorse the opinion expressed that the influence of digitalis in aortic stenosis is generally injurious. On the contrary, many physicians consider that in aortic stenosis digitalis is one of the most important remedies we have in aiding the heart to overcome the obstruction. Furthermore, the use of the word "or" instead of "and" makes the text read as if aortic stenosis and insufficiency were one and the same thing.

The statement made on page 342, that digitalis is eminently the medicine for a dilated rather than for a weak heart, is not, in our opinion, exactly correct. While there can be no doubt that in a certain number of cases of cardiac dilatation digitalis is most efficient, it is also certain that a weak heart, if such a thing exists aside from that produced by dilatation and fatty degeneration, is also benefited by this drug.

In the article on Jaborandi we find that this drug is heartily recommended in the treatment of uremia, but the danger of its

employment under these circumstances is not sufficiently emphasized.

We notice that in several articles additional information is given in brackets. Whether these brackets mean that this information has been provided by the chief editor in addition to that provided by the writer of the individual article, we do not know, as no explanation of the brackets is given either in the preface or elsewhere in the volume.

In conclusion, we may state that the small type and double-column arrangement has enabled the editor to compress within the 652 pages of Volume I an immense amount of information, much of which will doubtless be of very great value to practicing physicians, particularly those who, by lack of reading current medical literature or obtaining standard text-books on the subject, have unconsciously fallen behind in knowledge concerning the use of drugs.

**A TREATISE ON OBSTETRICS, FOR STUDENTS AND PRACTITIONERS OF MEDICINE.** By Edward P. Davis, A.M., M.D. Copiously illustrated with engravings and colored plates.

Philadelphia and New York: Lea Brothers & Co., 1896.

This new work on Obstetrics is a volume of 553 pages, including the index, and is based upon the author's experience as a practitioner and teacher of practical obstetrics. We presume that it was written to aid him in carrying out the successful plan of teaching which he has followed for some years past, and it will place in the hands of his and many other students the facts which he believes are most necessary for practicing physicians to know in connection with this branch of medicine. He has also recognized the importance of accompanying his descriptions in the text by a very large number of photographic illustrations taken from life, which seem to bring the text in closer contact with actual practice than is usual in books on this subject which are illustrated solely with diagrams. Not content to use only the ordinary photographic camera in preparing these illustrations, he has also included a number of Roentgen-ray pictures which give additional interest to his topic. The chapters in the book which strike us as being most valuable and carefully prepared are those devoted to labor and the development of the fetus, the first showing Dr. Davis's practical experience and familiarity with the teachings of both foreign and American obstetricians, and the second showing not only his touch but also that of Dr. Charles Dolley, who, we

are told in the preface, has aided in the preparation of this chapter.

While it is not possible to present a text-book which will contain a large amount of original matter upon a subject which has been so thoroughly written about as obstetrics, we think that Dr. Davis is to be congratulated upon having produced a book which includes nothing that can be considered as no longer of value, and which presents a summary of the best obstetric practice of the day in a concise and lucid manner.

**ESSENTIALS OF PHYSICAL DIAGNOSIS OF THE THORAX.**

By Arthur M. Corwin, A.M., M.D. Second Edition, revised and enlarged.

Philadelphia: W. B. Saunders, 1896.

This is a very small volume, printed on thin paper, and the text is arranged in a peculiar manner. We do not think we have ever seen a display of so many varieties of type, except in the catalogue of a type-foundry. The object of using these varieties has been to make headings and sub-headings, with the hope that by so doing the various facts connected with physical diagnosis may be the more readily picked up and absorbed by the student. The book is not one which will prove of value to the general practitioner, but, in connection with teaching by lecture or otherwise, will doubtless aid the student very materially. Outside of the class-room we doubt if it can be generally employed.

**THE PROCEEDINGS OF THE WEST LONDON CHIRURGICAL SOCIETY.** Seventh Volume. Session of 1894-95.

Edited by Richard Lake and L. A. Bidwell.

London: John Bale & Sons, 1896.

This is a small octavo volume of about 150 pages, containing a record of a number of interesting cases, extending all through the realm of medicine, which have been met with by the members of the Society whose proceedings it records; and the Society is evidently one composed of active clinicians who gather together rather with the object of making comparisons of their clinical experiences than of putting on record solely the results of scientific study and laboratory investigation.

**OBSTETRIC DIAGNOSIS AND TREATMENT.** By O. Shaffer, A.M., M.D. Wood's Medical Handbook Atlas Series.

New York: William Wood & Co., 1896.

We have already reviewed, in the columns of the *THERAPEUTIC GAZETTE*, the Atlas of Ophthalmology by Haab of Zurich, that upon the Nervous System by Jacob of Erlangen, that upon Fractures and Dislocations by

Helferich of Greifswald; and now we come to the fourth one of the series. This is a small octavo, like its predecessors, containing a very large number of colored cuts, many of which are very good and will aid the student, or physician in obtaining a clear idea of the physiological and pathological conditions which exist in pregnancy and parturition. It is, however, rather a volume for the teacher of obstetrics or for the active practitioner of this branch of medicine than for the student, unless he be far advanced in his studies. The ninth part of the book is devoted to a tabular arrangement of obstetric therapeutics, containing the name of the drug, its doses and its indications. The volume is distinctly German in its teaching and style, from beginning to end, and mirrors, as we suppose it is intended to, the personal teaching of its author.

### LONDON LETTER.

BY ST. CLAIR THOMSON, M.D., M.R.C.P., F.R.C.S.

For some months past I seem to have had to perform the melancholy task of commencing my letter with a necrology. Certainly there has lately been quite a holocaust of our distinguished seniors, and within a very short time we have had to lament Erichsen, George Johnson, George Humphrey, Savory, George Harley, and now in Benjamin Ward Richardson we lose, if not the most distinguished, at least the most many-sided, of our elder physicians. His death was sudden and took every one by surprise, for he was not only an ardent advocate of temperance, exercise, and hygiene, but himself carried out his principles so rigidly that we had, thoughtlessly perhaps, come to expect that he would live to be a "grand old man" of medicine, and an example of the correctness of his own views. But he died at the age of sixty-eight. On the day of his death he had just corrected the proofs of a forthcoming work of an autobiographical character to be entitled "Memories and Ideas," when he lost consciousness and never rallied. It would take too much space if I were to give even a catalogue of the leading features of his active life. In medicine alone he did more than enough to insure himself a reputation as a scientific worker; but the strictly professional field was all too small for his ceaseless energy. He was a pioneer of Public Health, at a date, too, when the cry of the

sanitarian was as the voice of one crying in the wilderness and the "Medical Officer of Health" was still in the womb of time. He founded the *Journal of Public Health and Sanitary Review*, and the well known aphorism which he placed on the title page—"National Health is National Wealth"—has become an established principle of social science. For the past twelve years he edited a quarterly magazine entitled the *Asclepiad*, full of original research, criticism, and quaint medical lore. From cover to cover he wrote every word with his own pen, and in themselves these twelve volumes are a testimony of his versatility. But neither medicine, literature, nor sanitation were sufficient for his many-sidedness. He was an ardent reformer, a temperance propagandist, a novelist, and somewhat of a transcendentalist philosopher; he was a cyclist and an authority on cycling; he lectured on dress reform; he designed the lethal chamber in the Home for Lost Dogs, where stray mongrels are painlessly put to death; he pleaded for the reform of our slaughter houses. His studies on anesthetics are well known, as well as his invention of local anesthesia by means of the ether spray; he even simplified and improved the method of embalming. But this brief catalogue of his work is getting too long. His versatility was too various to confine itself within any academic bounds, and he was never connected with any of the large teaching hospitals of London; his personal character was kindly, frank, generous, and humorous, and he was one of the most interesting specimens of wide learning in an age when we all seem to be threatened with mental myopia as a result of the limitation we are putting on our intellectual horizon.

Last month I epitomized Mr. Frederick Treves' methods of surgical procedure in abdominal operations; now under the title of "Cleansing and Cleanliness in Abdominal Surgery" we have Mr. Lawson Tait's views on the matter included under that title—and on a good deal else besides. For the celebrated Birmingham surgeon is in one respect like Mr. Dick, only instead of Charles the First's head it is Listerism which he is unable to keep out of his effusions. Mr. Tait, like the Scotch carter in the story, generally "sweers at lairge" against Listerism and antisepticism, making light of microbes, and becoming especially gleeful over the fact that Lister himself has renounced the spray as quite unnecessary. I had always understood that Mr. Tait was the apostle of cleanliness

pure and simple, and certainly the impression is abroad that he employs no antiseptic and no other purifying agents than soap and water. It is therefore with considerable interest that we read the following in the *Medical Press* of November 25th: "All instruments with sliding tubes, screws, or bended joints ought to be abandoned; every joint should be capable of being unshipped, and after every operation every instrument should be scrubbed with raw turpentine and a brush, and then well washed with soap and water. If this be done, immersion in cold tap water for the next operation is all that is wanted." So much for the purification of his instruments; now for the cleaning of his hands: "I do not fear the ordinary germ poisons at all," he writes, "but still I take the precaution of keeping my nails short and clean, and of washing my hands in raw turpentine the last thing before performing any operation, and then washing off the turpentine by ordinary soap and water." So, after all the redoubtable opponent of antisepticism turns out to be as Listerian as any of us! If we turn to the work on "Wounds, Ulcers, and Abscesses," by Professor Watson Cheyne, Lister's old interne, for many years his private assistant, and now the occupant of his chair of Surgery in King's College Hospital, we will find a remarkable similarity in the directions he gives for the carrying out of antiseptic technique. About the only difference is that Mr. Watson Cheyne employs a five-per-cent. solution of carbolic lotion for cleansing his instruments, and adopts some extra precautions in the way of employing an antiseptic lotion instead of tap water to flush his wounds. By the way, there is something suggestive of Bob Acres in Mr. Tait's denial of fear of ordinary germ poisons, though still he takes precautions. Why Mr. Tait and his allies should find any satisfaction in running tilts against what they are pleased to fancy is "Listerism," it is difficult to understand: if it would appease them I dare say the world would be quite prepared to give up the term "Listerism," for truth need bear no man's name. They can call it cleanliness, or what they like; but they may rest assured that the virtues of surgical cleanliness were never appreciated until Lister came on the scene, and that their "surgical cleanliness" would have remained as empiric—and therefore as apt to frequent error—as any old wife's rule of thumb, if Lister and his disciples had not been able to explain by bacteriology the rationale of their surgical procedures.

That Mr. Tait should waste his time in charging at wind-mills is the more to be regretted when we see what good work he can do: in this same address, for instance, there is much of practical value. One of the conclusions he holds strongly is that the more patients are separated the better; hence for the greater part of his practice he uses a separate room for each patient. Here is another point learned in his wide experience: "The fourth night is the critical night with all save hysterectomies, and with them this is not so definitely fixed. If an ovariectomy is all right on the fifth morning the chances of her going wrong are small indeed. But if you 'pack' them they will have hematoceles, stitch abscesses, pulmonary complications, mumps, and all sorts of secondary troubles, in proportion far greater than if you kept them absolutely one in each room." With regard to this I would only ask, why mumps? It would be very interesting to know why mumps should develop if cases of abdominal operation are crowded together; I have never seen such a complication in wards which were more than crowded with other varieties of operation. "Cleanliness in surgery," says Mr. Tait, "may be divided into general and specific. General cleanliness, such as that close attention to cleansing wards and all in them, the cleanliness of all linen, bed-clothing, and the personal cleanliness of the surgeon and the members of his staff, are matters I need not waste time over." He then goes on to describe the "specific cleanliness," such as I have sketched it—a free use of soap and water and raw turpentine. He hails with satisfaction all the wonderful inventions and devices of the modern operating theatre for securing cleanliness, for that cleanliness can be secured only by the work of women, "and women in themselves have not the slightest idea of cleanliness save on the surface, and unless they belong to the really well-educated classes."

In connection with antiseptic dressings it has been suggested that much of the trouble consequent on burns could be avoided by the use of an "antiseptic cage." This is an arrangement like the leg cradle in miniature, by which the burned surface is simply kept exposed to the air but protected from direct contact, so that it can easily be inspected and treated with lotions or powders, while all the trouble consequent on the adhesion of dressings is avoided. The importance of leaving wounds as open as possible is shown by the results obtained by Mr. Treves in compound

fractures of the lower leg. Once the fracture is reduced and the wound thoroughly purified, he leaves it (protected by a cradle) entirely exposed to the air, the only dressing being a handful of iodoform which is placed on the wounded surface. This is not washed away with any lotion; if any of it gets displaced the nurse has directions to simply add a fresh teaspoonful of the powder. No dressing whatever is placed over it, and the leg is left open to the air day and night,—proper precautions being of course taken that neither the body nor the foot of the patient be chilled.

One can generally find something suggestive in any address given by Dr. Goodhart. He recently gave one on "The Fringes of Disease," and in it we find some practical suggestions and some interesting speculations. He is inclined to scout the belief of the surgeon that if he only gets a cancer early enough and sweeps wide enough he is likely to be able to eradicate it. He narrates, among other vague cases which were on the "fringe" of various definite diseases, a case of fever lasting over eight weeks, subsequent to confinement, but quite unconnected with uterine trouble, in which there was a daily paroxysm of intermittent fever. It was not malaria, and he inclined to the view that it was influenza. He prescribed Warburg's tincture, and in twenty-four hours the fever ceased. Amongst other fringes of disease he indicated how much we have to learn about the decay of teeth, the affections of the nails, and ulcerative stomatitis in children. He thinks that many "woolly states of the intellectual centres might possibly sometimes receive an enlivening influence by a timely resort to the thyroid extract." In another case a patient had not a single symptom of myxedema, but was so unwieldy in weight that she could not move about; in a short time, by taking thyroid extract, she had lost 14 lbs., while generally improving in health. He refers to indefinite states of anemia associated with swellings: "Not at all alike are these to what we know as myxedema in their outward appearance, and many of which have nothing to do with it, yet possibly as many of them are very rebellious to iron and such things as are the remedies for anemia, a mild myxedema may be worth considering. I never think of exophthalmic goitre without marshalling before my mind's eye a very wide fringe indeed,—a sphere of influence that has something to say in the production of some of a very varied class of cases, such as morbid flushing,

morbid flushing, morbid sweating, tachycardia, abdominal pulsation, general tremor, and other emotional disturbances too numerous to mention." Indeed, he seems to look very respectfully on the ill-humors of the thyroid body, and thinks that the day may come when our congested livers, delicate chests, and weak hearts may have to take a back seat as diagnostic refuges, while thyroid congestion, sluggish thyroid, and cirrhosis of the thyroid may be the shelters of the future.

Amongst the larger addresses of the last month there is an interesting one by Mr. Bruce Clarke on "Some Effects of a Lack of Muscular Development." He limited himself to the effects which accrue to the organs inside the abdominal walls from a neglect of proper physical exercises. He endorses much that was first brought to public notice by Glenard with reference to enteroptosis, and shows how this condition is consequent on a slackness and want of tone in the muscles of the abdominal walls. The protuberant belly of advanced or middle life also depends quite as much on the weakness of these muscles as it does on the deposit of fat on the omentum and mesenteries. Many cases of muscular weakness, especially in young people, are apt to escape recovery owing to the real condition being overlooked. One young girl of sixteen, although nearly five feet five inches in height, did not weigh 84 lbs., was so thin and wasted that she could hardly walk for ten minutes without weariness and dragging in the back and loins. She had been advised to go abroad and not to overdo exercise. Mr. Clarke regarded her case as one entirely of muscular weakness, and as the treatment he ordered her is typical of what he recommends I will quote it in his own words:

"It was at first difficult to persuade her that she was capable of doing anything; and when I prophesied that in a few months she would be able to row with her brothers I am sure I was not regarded as a man of truth; but my prophecy was fully justified, and to-day she is capable of hours of continuous exertion, and is in good hard condition, weighing upwards of ten stone.

"The plan which I adopted was as follows: I ordered, to start with, five minutes' exercise for certain muscles, beginning with those of the back and abdomen, which was carried out by her maid; the back and abdomen were gently rubbed with a stimulating liniment, to impart a sensation of warmth, and then she was assisted to get up from the re-

cumbent position and return to it again without the aid of her arms. By the end of a fortnight she could do this alone, at least once an hour for twelve hours. Her appetite improved, and she was anxious to try to walk. I had refused to allow walking at first, because if my interpretation of the symptoms was correct, her viscera ought not to be dragged on without support. As soon as she found what rapid progress she was making she entered very fully into the scheme of her treatment, and proved herself very ingenious in suggesting little exercises. At the end of six weeks she desired to try to row, and was permitted to do so. Shortly after this a rope and pulley was rigged up for her, and by altering the weights she had to raise, and working sometimes one hand, sometimes both, the muscles of her trunk and limbs increased rapidly in firmness, and her appetite improved amazingly, and with the growth of her muscles her lateral curvature disappeared, and all weariness about the back and loins came to an end.

"Since that time I have on a good many occasions prescribed analogous movements in consequence of pains about the abdomen and back, and always with considerable advantage, though never perhaps with so striking a result as in the case just related."

It will be seen that here we have our old, reliable, though much neglected friend, the movement cure again.

In an article on the medical treatment of tic douloureux by Dr. Ewart, "resistance movements" and Swedish gymnastics are strongly recommended as tonic measures, and as having the advantage of diverting energy from the oversensitive nervous mechanisms while raising the general nutrition; these movements should be preceded by massage, and should only be gradually increased. As regards the direct medicinal treatment Dr. Ewart suggests that alterative treatment may, in genuinely gouty cases, be specially directed to the gout. The salicylates, the benzoates, sulphur, chloride of ammonium, and taraxacum are available, but none of them probably equal in efficacy the salts of iodine and mercury, and particularly their combination in the proportions of twenty to thirty minims of the solution of the perchloride of mercury, and of six to ten grains or more of the iodide of potassium. The iodide may be tried alone, and should then be given in sufficient doses: its action seems to be promoted by the addition of tincture of iodine in doses of fifteen to thirty minims. He nar-

rates several cases which were sent to the surgeon for the express purpose of operation; but in all of them the evil day has by medicinal treatment been postponed, in some perhaps indefinitely.

It is such a common event for orators to indulge in a cheap sneer at medical progress that it is interesting to read that Dr. Wadham has expressed the opinion that in order to be a good physician "a man must be acquainted with the medical science of the day, even though it may be destined to become the medical nonsense of to-morrow."

To any one who desires to know something about the quacks and quack mixtures of this country let me recommend a small shilling book which has just been published by the Savoy Press, 115 Strand, W. C., and entitled "Exposures of Quackery." It might even be useful to leave it about in the waiting room of one's office, in the vague hope that, tract-like, its winged words might now and then fall on fruitful ground. In its pages are revealed the ingredients of many of the chief nostrums of the day. Here, for instance, is the analysis of Sequah's Prairie Flower. "This wonderful and world-renowned preparation," as its circular remarks, "has been in use amongst the Sioux, Cherokees, Comanches, Apaches, and several other tribes of North American Indians for hundreds of years." This remarkable prairie flower turns out to be aloes, and in order to procure it the brave redskin must have journeyed to either the East or West Indies, for I believe the aloes is unknown in the native territories of the States. And so on through the chief nostrums, the principal ingredient in many of them turning out to be aloes! Scattered through the book are some amusing stories. Here is one of Dickens and Thackeray. When Charles Dickens was in the height of his splendid career as a novelist, Holloway—the notorious quack "professor," inventor of Holloway's Pills and Ointment (the first chiefly aloes, the second lard and olive oil)—sent him a check for \$5000, with an intimation that he might consider it as his property if he would insert in an early number of one of his works, then coming out in a serial form, some reference to the Holloway patent medicines. Dickens, to his honor be it said, promptly and indignantly returned the proffered bribe. Upon hearing of this incident, Thackeray remarked, with the quick sarcasm of which he was master, that if he had been in Dickens' place he should have killed the villain of the novel with an overdose of Hol-

Holloway's Pills, and thus have secured the \$5000. On another occasion the hustling "Professor" did succeed in securing an introduction to Thackeray, at a large reunion of distinguished people. Thackeray appeared to understand the name imperfectly, and complimented the "Professor" in the same strain as he would have done in the case of a distinguished military officer. Holloway, confused, had to explain that he was not a general; but merely "Professor" Holloway. "Oh! well," observed Thackeray, "I made a very natural mistake, for you, too, must have killed thousands of people." This is the same Holloway who, having made his pile, endowed some institutions and was knighted by the Queen! One institution was at least appropriate, if intended as a delicate compliment to the people who believe that his pills and ointment will cure every human malady, viz., an asylum for lunatics.

However, in spite of exposure after exposure, the sale of so-called "patent medicines" goes bounding upwards like African gold shares during the booming season. The papers follow with their record of poisonings. Possibly the fact that it is not toxic is one of the reasons why aloes is such a safe "reef" to work.

The chair of Forensic Medicine in Edinburgh is about to become vacant through the retirement of Sir Douglas Maclagan. He is close on eighty years of age and is still lecturing. Sir Douglas comes of a distinguished family, his brother being Archbishop of York. The chair is in the patronage of the Crown and is worth \$4000 per annum.

And this reminds me that there is at present a great upheaval in the Athens of the North in the sphere of medical journalism. The old and well known *Edinburgh Medical Journal* has changed publishers; it will be continued with new editors from another publishing house. The opportunity has been taken for inaugurating a new journal with the more comprehensive title of *The Scottish Medical and Surgical Journal*. It will commence in January. Both journals announce a strong list of contributors, but it remains to be seen if they can maintain a high standard without having recourse to the proceedings of societies, and such like, to fill their pages. However, there is plenty of talent at present in Edinburgh, and plenty of young energy in the profession. A generous rivalry is the best stimulus, and the medical public will be the gainers.

Last month I wrote that we were on the

eve of the election of direct representatives to the Doctors' Parliament—otherwise the Medical Council. The results are just published and the three successful candidates for England are a London general practitioner, a Liverpool practitioner, and another London practitioner who is a distinguished leader writer on the staff of the *Lancet*. Rightly or wrongly, he has frequently been referred to as the *Lancet's* nominee. Anyhow, these three are undoubted Progressists and they will do their best to make things hum in the fossilizing Council, although they are in such a marked minority. Of the thirty members in the Council twenty-five are the nominees of the various universities and colleges of the Kingdom, while the profession is only allowed to have a voice directly in the return of the five direct representatives—three for England and Wales, and one each for Scotland and Ireland.

The chief journals have been jesting gently at the Hospital Reform Association, but I see that it is working ahead; if it should ever have any success I think it might claim to be the Jack-the-Giant-Killer of reforming associations. Our new Lord Mayor—it is an annual office—has suggested that he might inaugurate a large scheme next year to celebrate the sixtieth year of Queen Victoria's reign by starting a collection which would pay off the debts of the London hospitals. He has promptly been met by an avalanche of objectors. The provincial people object to being drained for metropolitan charities, while they have their local hospitals to support; and many point out that the numerous hospital committees are only waiting to get a few debts paid off in order to launch out into all sorts of wildcat schemes. In fact, it is suggested that they would at once get into debt in order to have some ground on which to found an appeal to the generous public for maintenance! There are very few institutions which do not put their indebtedness in the forefront of their claims for recognition, and in the rivalry between them it would not do for one to be left behind!

To revert for a moment to provincial schools—of which I am reminded by mentioning Edinburgh—I see that the progress of the medical school of Manchester, in connection with Owens College, is reported to be simply phenomenal; the entries this year are equal to several of the largest schools in London, and far surpass the majority of metropolitan entries. There can be little doubt that the chief cause of this is the

facilities afforded in Manchester for obtaining the degree of M.D. In London the average student can only hope to obtain the qualifications of M.R.C.S. and L.R.C.P., and that, too, with quite as hard work as is demanded by the provincial universities. This appears decidedly hard on the London schools, for although we have the University of London its tests are so stringent that only a minority can ever hope to obtain its degrees.

I have given you the result of the case of *Beatty vs. Cullingworth*, where a lady prosecuted a leading London gynecologist for—according to her story—removing an ovary against her wish. She lost her case, but now report has it that she has lodged an appeal, and it is possible that she may persevere, for it is rumored that the money for her case is forthcoming from a body of persons who hold the extreme view that a woman should rather die than submit to removal of the ovaries. Dr. Cullingworth's expenses were considerable, so much so that an appeal was made to his *confrères* to help him. It is gratifying to know that this appeal was so generously met that within a very few days the list was closed, and further subscriptions refused.

Our profession has been very much to the front lately in the law courts. Here is another case which illustrates some of the difficulties which we may have to deal with in a medico-ethical way. The facts are briefly as follows: A doctor was called to a certain house, and was asked by his employer to see and prescribe for her maid servant, and report to the employer upon the girl's state of health. In consequence of the doctor's report the servant was dismissed. She commenced an action for slander against the doctor, who finally, upon legal advice, settled the matter by paying her a solatium and the costs. This case came before the solicitors of a Medical Defense Society and they advise that a medical man paid by his employer to attend upon the servant of the employer (the servant not objecting to being attended by the doctor) might divulge to his employer the result of his attendance, that being a privileged communication; but if the report is made in the presence of, or to, any other person than the employer (as happened in the above instance), the report is not privileged, and the matter may become actionable. They further expressed an opinion that a doctor consulted by an employer in reference to the health of a servant should obtain the written consent of the servant before prescribing or

divulging the result of his examination to the employer in such cases where the servant might be likely to object to his doing so. All of which goes to show that to be called in to see a maid servant is no matter to be lightly undertaken. Many families think that the unfortunate medico should never charge for his attendance on the domestics. So he now has the chance of a double loss—no fee, and perhaps a "solatium" and costs!

Dr. Jameson, the hero of the Transvaal raid, has been allowed out of prison. He had an operation for hemorrhoids performed while in durance vile, but his general health became undermined and is said to be anything but satisfactory.

Sir William McCormac, the President of the College of Surgeons, is slowly recovering from a long attack of pleuro-pneumonia. A localized empyema has been discovered and he has had to undergo resection of a rib in order to give it vent.

It is regrettable to notice in the last report of the Medical Officer of Health for the City of London that reference has to be made to those "abominations known as sewer ventilators." The main sewers are merely ventilated by means of iron gratings in the roadways; the consequence is that under the best conditions the air in the streets—and it is only from the street-air that our houses are ventilated—is continually befouled by sewer-gas, while under certain conditions (as in summer-time, or when the sewers are being flushed) the streets become simply pestilential from the stench of sewer-air. The air in London is surely sufficiently fouled by our swarming population and our horses without ventilating our sewers underneath our very noses.

The well-known writer Sir Walter Besant has lately been giving an address and indulging in the most high-flown rhetoric androdomontade on the beauties of the metropolis. He must be personally a most insensitive person if his nose does not reveal to him the condition of things; he must be most unobservant if he does not see it for himself; his knowledge of London (he has written voluminously about the city) must be of the most superficial character; and his knowledge of foreign cities must be *nil* if he does not realize that London is being rapidly left behind in civic health and beauty. The streets are filthier and worse lighted than many continental cities and, in this respect, are not to be compared with most of our provincial towns. Our house-refuse is removed

only once a week, and for seven days we collect it in so-called "dust-bins" to putrefy in our areas; our drinking-water—drawn from the Thames after that river has received the sewage of several up-stream towns—has recently been condemned as dangerous; and now we take our walks through streets which are hardly more than open sewers! And this is the city Sir Walter Besant compares to a beautiful woman, only rather a large one! Certainly she is so large as to threaten to be quite unwieldy, and like Mr. Lawson Tait's patients she is decidedly in want of cleansing.

Our Local Government Board fulfills many of the functions which in another country would be carried out by the Ministry of Public Health. The question of the spread of disease by oysters comes into the sphere of action of the Board in question, and they have just issued a report on the subject which confirms many of the suspicions which have been cast on what the penny-a-liner likes to refer to as "the succulent bivalve." I have seen the report, though I cannot say I have read it; its voluminous character acted as a deterrent. But it appears so extensive and exhaustive that I think it is bound to attract considerable attention. The subject is considered from many points of view, not the least interesting being the comparison of the bacteriologists' researches with those of the sanitary engineers. The report shows that while there are some spots around our coasts where the oyster culture is carried on in beds which are above suspicion, there are many other regions where the oyster beds are polluted with sewage. Of course the whole oyster trade will suffer for the shortcomings of even a few places; and it is difficult to see how confidence is to be restored short of a government inspectorship. In this land of free trade in everything there is always great objection offered to a fresh interference by our grandmother, the State, in what has hitherto been private enterprise.

Less than a dozen cases of drainage of the pericardium have been recorded during the best part of a century. One has been added to the list by Mr. Betham Robinson. Part of the sixth rib had to be resected and two quarts as measured were evacuated; irrigation was decided against owing to the patient's feeble condition. Although rare, such cases when analyzed show a good proportion of recoveries, viz., five out of eight.

The expression "every rib in his body broken" was very nearly shown to be practi-

cally a possibility by a case recorded recently in the Clinical Society. At the post-mortem on a man who had been injured by an accident in a quarry, there were discovered the following fractures: on the left side, comminuted fractured end of clavicle; fracture of all the ribs, some of them being broken in two or more places; on the right side, single fracture third rib, sternal end; 4, 5, 6, 7, two fractures sternal end and angles; 8 and 9, single fractures. All the organs were normal with the exception of the right kidney, which showed a blood calculus in the lower part. Yet all these fractures occurred in a man of seventy-three years, who survived his accident for six weeks, and then died in a fit, apparently from syncope. One speaker at the subsequent debate pointed out that in old people he found that fractured ribs did better in the sitting posture than in bed; while another pointed out that the patient in question was a teetotaler, and that in abstainers cases of non-union or delayed union were rarely met with.

Preparations are in active progress for the meeting of the British Medical Association next year in Montreal; but I dare say you hear about the preparations on your side. The editor of the *Journal*, Mr. Ernest Hart, is in such indifferent health that he has given up his London house.

In my last letter there was a reference to creosote and guaiacol. It has been further recommended that they always be given on a full stomach, and their solution in alcohol or glycerin further diluted by mixing with some bland fluid such as milk. Pills and capsules, as being more likely to irritate the stomach when their undiluted contents are liberated, should be regarded with suspicion. In the treatment of chronic bronchitis, ipecacuanha has again been recommended when administered in the form of a spray; this is carried out by frequent administrations of ipecacuanha wine, three or four times a day. At each sitting one-half to one drachm of the drug is used, but the patient is directed not to swallow the wine. Amongst the occasional disadvantages were vomiting, and spasmodic dyspnea if the drug were used pure. It is not suitable for cases of asthma. The ipecacuanha spray is particularly suitable for cases of dyspnea with tenacious sputum. At the medical meeting where the above was advanced other drugs came in for their share of commendation in the treatment of chronic bronchitis: among these were cod-liver oil, carbonate of ammonium—which may be ad-

ministered in the form of the ammoniated tincture of iron and quinine—external applications of turpentine, and inhalations of oxygen. The effects of drugs on the secretion of the mucous membrane of the trachea was originally worked out on animals by Rossbach. These observations have recently been repeated by Dr. Calvert (*Journal of Physiology*, Aug. 21, 1896). The trachea of a cat under the influence of chloroform or urethane was opened, dried with blotting paper, and the interval of time before the surface became again covered with secretion ("interval of secretion") noted. The drug to be investigated was then slowly injected into a vein of the leg, and the interval of secretion again noted. Sodium carbonate increased the secretion; this result is directly opposed to Rossbach's observations. Iodide of potassium and emetine increased the secretion. Saponin, which is identical with senegin, the active principle of senega, in small doses did not increase the secretion, while in large doses it diminished it. Cold, as in the form of an ice-bag to the abdomen, led to an increased secretion, while heat, hot poultices, or fomentations applied to the abdomen, diminished the amount of secretion from the tracheal mucous membrane, but in neither was the effect as marked as in Rossbach's experiments.

How is the word enema pronounced in the States? I think I am safe in saying that on this side the majority of practitioners rest the accent on the second syllable and so render it *énéma*. If so, then use and wont have been ruled to be wrong; for the *British Medical Journal* quotes a long string of authorities to prove that the accent should be on the antepenultimate. Etymology is not the law of English pronunciation; we say *órator* and *sénator*, in defiance of the Latin quantity, because it is the tendency of our language to throw the accent as far back as possible consistently with ease of articulation. I need not, therefore, enter into all the reasons which cause our contemporary to give its weight to the pronunciation I have mentioned, but as I see that it quotes Billings' and Gould's Dictionaries in its favor I suppose we will in future be agreed on both sides of the Atlantic to speak of an *énéma*.

When I commenced this letter I had to refrain from a medical *cause célèbre* as it was still in the law courts; it is now over and both the trial and verdict have been the principal subject of discussion in medical circles. The following are the circumstances

of the case: One of the masters of the great public school of Harrow, by name Welsford, was attended by the school physician, a certain Dr. Stiven, for an illness which the latter said was an ordinary attack of indigestion. Acting on this diagnosis he prescribed aperients and then opiates, and ordered the patient's stomach to be vigorously rubbed. The patient continued to get worse, and when he and his anxious wife hinted at a consultation and suggested the word "appendicitis" they were scoffed at by the medical adviser for their scanty and dangerous knowledge of medicine. Still Mr. Welsford got no better, and when his brother arrived, the latter, being a physician, discovered a large lump in the groin and an undoubted case of appendicitis. Mr. Victor Horsley operated, and none too soon. Now we come to the part of the story where the *cause célèbre* commences to develop. Dr. Welsford was so indignant at the treatment his brother had received that he did not refrain from telling all and sundry, in and about Harrow, what he thought of the school doctor; he not only said what he thought, but—rash man—he also wrote it! Dr. Stiven took out an action for libel and slander against him, claiming heavy damages. After seven days' trial he obtained a verdict, but with only \$375 damages. I must explain the true inwardness of this verdict. Dr. Stiven's practice was large and lucrative and he claimed heavy damages as he said his position had been seriously injured by the defendant's slanders. The defendant pleaded justification. Now, what the jury's verdict amounts to is this: that Dr. Stiven's treatment was wrong, or that he was so little right that \$375 was quite enough for him; and that Dr. Welsford was wrong too in showing a want of good feeling and some malice in the way in which he spread his opinion of Dr. Stiven's incapacity. The case reminds me very much of a head-master of my own youth: whenever two boys came before him complaining of one another, he almost invariably settled the difficulty by "switching" both of them. All the daily papers are full of the morals to be drawn from this case; the *Times* says that it shows that you may send away your physician, but you must not publish the reason why you do so; the *Daily News* says that the verdict will help to curb the flow of personalities between members of the medical profession, who have hitherto been the licensed libertines of gossip. That's pretty severe on us. This great daily goes on to remark that the delightful flow

of conversation which is supposed to be so cheering in the sick-room must henceforth be checked; that only politicians in future can indulge in unbridled personalities; and that doctors will soon have to be as careful as editors. Most of the other papers have a side slap at us, and the general public appear to feel rather disgusted with our tendency to depreciate one another. And they are quite right, too.

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

This year's course of lectures on the History of Medicine, given by Professor Laboulbène at the Faculty of Medicine, is devoted to medical journalism. Though the first journalist, Théophraste Renaudot, to whom a statue has recently been erected in Paris, was a physician, the first real medical publication appeared in Paris twenty-six years after his death on the 28th of January, 1679, edited by Nicholas Bligny. The second medical journalist was Jean Paul de la Rogue, a native of Albi, a town in southern France, who edited a paper called *Journal de Médecine et Observations des plus Fameux Médecins, Chirurgiens et Naturalistes de l'Europe*, etc. (1683). This work met with but little success, and was followed by a *Journal de Médecine* in 1686, and in 1695 by *Le Progrès de la Médecine*, which appeared every month up to 1709.

In 1880, according to Professor Laboulbène's estimate, the medical journals in existence numbered 785. By 1895 they had increased in number to 1380, and even then it was doubtful whether all were known. The papers are, by countries, as follows:

France: Paris, 191; provinces and colonies, 95; a total of 286.

Europe: German Empire, 168; Italy, 140; Great Britain, 101; Russia, 86; Spain, 47; Austria, 45; Belgium, 31; Holland, 16; Switzerland, 13; Sweden and Norway, 9; Danubian principalities, 7; Turkey, 2; Greece, 2; a total of 667.

Asia: India, 25; China and Japan, 30; total, 55.

Africa, 2.

America: United States, 343; South American States, 17; Canada, 4; Mexico, 2; Brazil, 1; total, 367.

Oceanica, 3.

Death during the past year has been busy in the Faculty of Medicine of Paris, number-

ing among its victims three professors and four assistant professors. Less than a week ago a new name was added to the list, that of Dr. Straus, Professor of Experimental Pathology. Professor Straus was born at Dampach, in the province of Alsace. His medical studies were performed at Strasburg, where he was interne of the hospitals and assistant professor. This latter position he obtained in 1869, when but twenty-five years of age. The Franco-German war of 1870 induced him to leave his native place, and in 1874 he was named *chef de clinique* at the Paris Faculty of Medicine. Later he studied with Pasteur, and in 1882 went to Egypt with several others as a commission to study the cholera at that time prevalent there. When Vulpian died, Dr. Straus was appointed to succeed him, and devoted his course of lectures to bacteriological work. To Dr. Straus is owed the characteristic diagnostic test of glanders, the action on the testes of the guinea-pig. When this animal is inoculated with a secretion supposed to be due to glanders, the testes will in a few hours become enormously enlarged in case the diagnosis was correct. Last year Dr. Straus published an exhaustive treatise on tuberculosis and its bacillus. He was a member of the committee charged with editing the Annals of the Pasteur Institute, as well as of the Archives de Médecine Expérimentale et d'Anatomie Pathologique.

*La Semaine Médicale* publishes as a supplement to one of its recent numbers two maps giving, by means of shading, the relative proportion of physicians to population in France and in Paris. In Paris, naturally, the number of physicians is greatest in the neighborhood of the Chaussée d'Antin, the Madeleine, and the Champs Elysées, where it is from three to more than six per thousand. On the other hand, two of the outlying and poorer quarters of Paris, known as La Gare and Saint-Fargeau, contain less than one physician to every ten thousand. In the provinces it is seen at a glance that the presence of large cities brings up the proportion of their immediate neighborhood. Such influences being left to one side, it may be said that there are more physicians in the south than in the north of France. This would seem to be due to the fact that the south of France furnishes more medical students than the other regions. Outside of the large cities, the proportion would seem to be about four to five physicians to every ten thousand of the population. In some parts of Brittany, how-

ever, the proportion falls below one to every ten thousand; and in several other regions it remains at from one to two to every ten thousand. In Brittany, indeed, there are some cantons of 20,000 inhabitants without a physician. Of course, the trouble from which the French physicians suffer is the desire they all have to live in Paris, or in some large town at least. It is this which has caused so much irritation in regard to foreign physicians practicing in France. At a dinner given a short time ago by the Syndicate of French Physicians, the Dean of the Paris Faculty of Medicine, Dr. Bronardel, advised young French graduates to emigrate to Canada, where, he had been advised, there would be a good opening for them.

At a recent meeting of the Société de Chirurgie, Dr. Segond reported a curious case where a primary cancer of the liver was taken for a fibro-myoma of the uterus before the operation. Laparotomy having been performed, Dr. Segond discovered that the tumor was a prolongation of a hepatic tumor. As the pedicle was narrow, he decided to remove the mass after ligation. The patient died of shock twenty-four hours later. Only twelve other cases are known when primary cancer of the liver has been removed.

---

#### DISLOCATION OF SHOULDER-JOINT.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Nearly all the text-books on surgery give three methods of reducing dislocations of the shoulder-joint, viz: the old method of extension (Cooper's), with the heel in the axilla as a fulcrum; Kocher's method by rotation and manipulation; and Malgaigne's method of outward or upward extension. It is the form of *outward* extension to which I wish to call attention.

About two years ago a large Irishman in a state of intoxication was brought to my office with a subcoracoid dislocation of about twelve hours' standing. As he was decidedly drunk, I tried extension of arm with heel in axilla without anesthesia, but without result. I then had him chloroformed to full anesthesia. During the administration of the anesthetic he got moved far away from the side of the lounge on which it was necessary for him to lie. I caught him by the dislocated arm just above elbow and endeavored to pull him nearer to me, and before I had moved him I was delighted to feel the head of the bone slip into its place.

Another opportunity was offered a few days since. A patient presented himself with a subglenoid dislocation of less than one hour's duration. He was chloroformed, and I seized his arm above the elbow, straightened it out at right-angles to the axis of the body, and then endeavored to pull or draw the patient directly toward me. The reduction was effected before I had moved the patient, a light man, from his position on the cot.

The principle is the same as that of Malgaigne, but the application (that of dragging the patient toward the operator) is different. No counter-extension has been required—the patient's weight has proved sufficient. I don't know that the procedure is applicable to backward luxations, but it has been eminently satisfactory in the cases described.

The method, in a few words, is this: Chloroform the patient, and then place him about eighteen inches from the side of the cot or bed on which the operator stands (this to prevent his being jerked off); then seize the arm above the elbow and raise it upward toward the patient's head until it is at a right-angle to the axis of his body, and pull the patient directly toward you as though you were going to pull him off the bed. This does the work before the patient is moved from his position.

Respectfully,

JOHN W. MECK, M.D.

CAMDEN, ARK.

### Notes and Queries.

---

#### THE FIRST OVARIOTOMY.

According to "Memorials of the Faculty of Physicians and Surgeons of Glasgow," by Alexander Duncan, the first ovariectomy was performed by Mr. Robert Houston, of Glasgow, in 1701, or more than a hundred years before the operation of Ephraim McDowell, of Kentucky, who is generally credited with being the earliest ovariectomist.

The following account of Houston's operation is quoted by the *Quarterly Medical Journal* from Mr. Duncan's book. It was published in the thirty-third volume of the *Philosophical Transactions*, London, 1733. Whether the claim that this was the first recorded ovariectomy is true or not, the account is interesting reading.

August, 1701, I was in the Country with a Patient, the Lady Anne Houston, Wife to Sir John Houston, Baronet, in the Shire of Renfrew, ten miles from Glasgow, North Britain. This charitable lady pressed me with

great Earnestness to visit a Tenant's Wife, who lay bed-ridden of an uncommon Disease, which no Physician or Surgeon who had seen her could give any Name to, or account for. She informed me that the ablest of that Country had forsaken her, and declared her incurable, so that I could lose no Reputation by the Result of my Endeavors.

In order to oblige this worthy lady, and in Compassion to the Distress of a poor Woman in so deplorable a Condition, deserted and given over on all sides, I went, determined to do everything in my Power for her Relief. She was in the 58th Year of her Age, her name was Margaret Millar. She inform'd me that her Midwife in her last lying-in at 45 Years old, having violently pulled away the Burthen, she was so very sensibly affected by a Pain, which then seized her in the left Side, between the Umbilicus and Groin, that she scarce ever had been free from it after, but that it had troubled her more or less during thirteen years together; that for two Years past she had been extremely uneasy, her Belly grew very large and a Difficulty of breathing increased continually upon her; insomuch that for the last six Months, she had scarce breathed at all but with the utmost Difficulty. That in all that Space of Time, having quite lost her Appetite, she had scarce eat so much as would nourish a sucking Child, and that for three Months together she had now been forced to lie Constantly on her Back, not daring to move at all, to one side or other.

This Tumor was grown to so monstrous a Bulk that it engrossed the whole left Side, from the Umbilicus to the Pubes, and stretched the Abdominal Muscles to so unequal a Degree that I don't remember ever to have seen the like in the whole Course of my Practice. It drew towards a Point. Her being so long confined to lie continually on her back having grievously excoriated her, added much to her Sufferings, which with want of Rest and Appetite, had wasted her to Skin and Bone, as the poor Woman herself expressed it. Indeed she needed not have told me so, my Eyes were too faithful Witnesses of her low and wretched Condition.

Scarce able to speak out, she told me that having heard much of my Success, she had strong Hopes of Relief, provided I would try at least and do something in pity of her Affliction. I answered her that I was willing, but afraid, in her low State, she would not have Strength to undergo a large incision; that in order effectually to relieve her, I must be obliged to lay open a great Part of her Belly, and remove the Cause of all that Swelling; she seemed not frightened, but heard me without Disorder, and as if inspired with sudden Courage, pressed and urged me to the Operation.

I drew (I must confess) almost all my Confidence from her unexpected Resolution, so that without loss of Time, I prepared what the Place would allow, and with an Imposthume Lancet laid open about an Inch, but finding nothing issue, I enlarged it to two Inches, and even then nothing came forth but a little thin yellowish Serum, so I ventured to lay it open about two inches more. I was not a little startled, after so large an Aperture to find only a glutinous Substance bung up the Orifice. All my difficulty was to remove it; I try'd my Probe, I endeavored with my Fingers, but all in vain; it was so slippery that it eluded every Touch, and the strongest hold I could take.

I wanted, in this place, almost everything necessary, but bethought myself of a very odd Instrument, yet as good as the best in its Consequence, because it answer'd the end propos'd. I took a strong Firr-Splinter, such as the Poor in that Country ordinarily used to burn instead of Candles; I wrapt about the End of this Splinter some loose Lint, and thrust it into the Wound, and by turning and winding it, I drew out some two Yards in Length of a Substance thicker than any Gellie, or rather like Glue that's fresh made and hung out to dry; the Breadth of it was above ten Inches; this was followed by nine full Quarts of such Matter, as I have met with in Steatoma-

tous and Atheromatous Tumors, with several Hydatides of various Sizes, containing a yellowish Serum, the least of 'em bigger than an Orange, with several large Pieces of membranes, which seem'd to be parts of the distended Ovary. Then I squeeze'd out all I could, and stitched up the Wound in three Places, almost equi-distant; I was obliged to make use of Lucatellus's Balsam, which was made by her Lady for the Use of the Poor; with this Balsam I cover'd a Pledget the whole Length of the Wound, and over that laid several Compresses, dipp'd in warm French Brandy, and because that I judg'd that the parts might have lost their Spring by so vast and so long a Distention, I dipt in the same Brandy a large Napkin four times folded, and applied it over all the Dressings, and within a couple of strong Towels which were also dipt, I swathed her round the Body, and then gave her about four ounces of the following Mixture which I had from her Lady:

℞ Aq. Menthae, 1 lb. fs.  
Aq. Cinnamoni fert., 1 lb. ifs.  
Syr. Diacodii, 3 vi. M.

The Cinnamon Water was drawn off from Canary and the best Cinnamon; indeed it was the finest and most fragrant Cinnamon Water I ever tasted; of this Mixture I ordered her two or three Spoonfuls four times a day.

Next morning I found her in a breathing Sweat, and she informed me with great Tokens of Joy, that she had not slept so much, nor found herself so well refresh'd, at any Time for three Months past. I carefully attended her once every Day, and as constantly dressed her Wound in same Manner as above, for about eight Days Together; I kept in the lower Part of the Wound a small Tent, which discharged some Serosities at every Dressing for four or five days. But Business calling me elsewhere, I left her, having first instructed her two Daughters (both Women, who carefully attended her) how to dress her Wound, and told 'em what Diet I thought most proper, enjoining 'em strictly to observe what I order'd.

Her chief Food was a strong Broth made of an old Cock, in each Porringer of which was one Spoonful of the Lady's Cinnamon Water; this was repeated four times a day, and gave her new Life and Spirits.

After three Weeks Absence I called at her House, and finding it shut up, was a little surpriz'd, but had not gone far before I was much more surpriz'd when I found her sitting wrapt up in Blankets giving Directions to some Laborers who were cutting down her Corn.

She amended apace to the Admiration of everybody thereabouts, recovered surprisingly, and lived in perfect Health from that time, which was in August, 1701, till October, 1714, when she died in ten Days' sickness.

Some pathological observations follow, and the paper finishes with a bibliography of ovarian tumors.

Houston's case of ovariectomy is notable, not only as being the first recorded, but for being performed in the absence of proper instruments and under apparently ludicrously unfavorable conditions, yet with a success which could not have been surpassed by a Keith or a Spencer Wells with all modern appliances and means aseptic and antiseptic to boot.

It is noteworthy that in this account no mention is made of the method of dealing with the pedicle, or of the time of removing the stitches from the abdominal wound.—*Boston Medical and Surgical Journal*, Nov. 5, 1896.

### SOME IMPORTANT FACTS ABOUT CHLOROFORM.\*

By H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia.

The effects of chloroform upon the vital functions has been for many years a subject of hot dispute between various surgeons and pharmacologists. On the one hand has been the school originally led by Syme of Edinburgh, which has asserted that death or dan-

ger from chloroform lay in failure of the respiration and that this was the function to be watched while chloroform was being used; on the other hand the so-called London school has asserted that death arose from cardiac failure and that the pulse was the thing to be watched during the use of chloroform. The number of clinical and laboratory researches which have been carried out to determine which of these opinions was correct has been very great, both in England and in America, but it has only been within the last ten years that the greatest and most competent studies have been undertaken, of which the best known is the series made through the munificence of His Highness,

\* A paper read before the College of Physicians of Philadelphia, Jan. 6th, 1897.

the Nizam of Hyderabad, in India, and known as the "Reports of the Hyderabad Chloroform Commissions Nos. 1 and 2." The conclusions of the first commission having been criticized adversely because it asserted that the cause of death was respiratory failure, a second commission was formed, and under a grant of \$5000 from the Nizam, Dr. T. Lauder Brunton of London was sent out to direct the second investigation. Although a teacher of the theory that death from chloroform is due to cardiac failure, this gentleman returned to England converted to the idea that the cause of most of the fatal accidents under this drug is respiratory failure, and the conclusions of Commission No. 2 were once more criticized by numerous clinicians and pharmacologists in England and America. About this time the author and H. C. Wood published a paper in which they expressed their belief in the powerful depressing effects produced by chloroform upon the heart; and MacWilliams of Glasgow proved by experiment that chloroform without doubt causes cardiac dilatation and enfeeblement. Shortly after this the author of this article was asked by the Government of His Highness the Nizam, through Colonel Edward Lawrie, the Residency Surgeon, to carry out a series of studies designed if possible to reconcile the contradictory results reached by the Hyderabad Commissions and other investigators, and simultaneously Gaskell and Shore in Cambridge University, England, were asked to do likewise. The result has been to confirm in every way the results of all previous studies in one respect, namely, that the primary action of chloroform, on the vital functions of circulation and respiration, is greatly to depress the vaso-motor system, thereby causing an extraordinary fall of blood-pressure. Gaskell and Shore, to be sure, assert that anesthesia can be produced by chloroform without causing this fall, but the author has never been able to do so. They also believe that the fall is chiefly a result of cardiac failure. With this view the author dissents, because their experiments upon which these assertions are based were too complex to give positive results; and second, because his own studies and those of others show the vaso-motor system to be depressed. There is of course some cardiac enfeeblement and dilatation, which adds to the fall of pressure.

As with other discussions in medicine, the truth of the question as to whether chloroform causes death by respiratory failure or

cardiac failure lies as it were half-way between the two antagonistic forces; and, further than this, the somewhat startling statement may be made that it is not directly due, in the majority of cases, to either of these causes. On the contrary, *the cause of death from chloroform is usually vaso-motor depression*, whereby the arterioles allow the blood to pass too freely into the great blood-vessel areas which are found in the capillaries and veins, and as a result the man is suddenly bled into his own vessels as effectually as if into a bowl. When it is remembered that the capillary network of the body will, with the relaxed veins, hold many times the normal quantity of blood, and when it is remembered that we can inject salt solutions into the vessels to the extent of several times the normal quantity of blood without raising the blood-pressure, it at once becomes evident that the complete vascular relaxation caused by chloroform results in failure of all the vital functions, not because the drug has paralyzed the heart or respiratory centre, but because these parts are deprived of blood by its stagnation in the widely dilated capillaries and abdominal veins. Recent studies by Leonard Hill on "The Physiology and Pathology of the Cerebral Circulation" showed that this was the case, for he asserts that when the blood was no longer flowing to the respiratory centres the heart was still beating, because its coronary arteries, being lower down, were more easily supplied by the small blood-stream received by the heart from the veins. These studies are proved by the experiments of myself and my assistant, Dr. Thornton (THERAPEUTIC GAZETTE, October, 1893), by every tracing of the Hyderabad Commissions, and all other tracings we have ever seen. We may conclude, therefore, that while chloroform without doubt acts as a powerful depressant poison to the respiratory centre and the heart, in the same manner as it paralyzes all living protoplasm when applied in excess, that when properly given by inhalation it produces a death equivalent to that resulting from hemorrhage, which is a failure of the respiration not so much from a direct depression of the respiratory centre as from its starvation of blood; and while the tendency of the drug is to depress and dilate the heart, just as it dilates the vessels of which the heart is merely a highly specialized part, the failure in the pulse rests upon vaso-motor palsy, the patient becoming pulseless because the heart has not any blood to pump.

Let us see what evidence supports this

view: First, we have the laboratory tracings of many independent investigators extending over many years and made in all parts of the world, all of which show a fall of blood-pressure. Among these may be named Bowditch and Minot of Boston, Coats, H. C. Wood, Gaskell and Shore, the Hyderabad Chloroform Commissions, the studies of Wood and myself in 1889 and 1890, and of myself and Thornton in 1892 and 1893. They are confirmed by Hill, who has seen the abdominal vessels engorged with blood under chloroform, the medulla almost bloodless and the heart still pumping though respiration had ceased. They are confirmed by my own experiments, in which I proved that even after the respiration had stopped and the carotid was empty, and the dog apparently dead, he could be resuscitated by visceral compression and artificial respiration, and by inversion whereby the blood left the dilated abdominal veins for the heart and brain. Again, if a needle was inserted through the chest-wall the heart was found to be beating, for the needle moved to and fro; and finally if the chest was opened the heart could still be found beating feebly—dilated, it is true, but beating.

So much for the laboratory evidence. What have we in clinical evidence? Equally positive proofs of vaso-motor palsy, and none of death being purely cardiac or respiratory. For years Chisholm of Baltimore and later Howard Kelly and a large number of others have used inversion with compression of the floating ribs in artificial respiration, which has forced the blood into the chest and saved life again and again. For years the literature of medicine has teemed with reports of death from chloroform while the patient was sitting up or half recumbent, because the blood-paths being dilated this posture favored anemia of the vital centres. Again, it has been proved both experimentally and clinically that the best vaso-motor stimulant—belladonna or atropine—given before the chloroform, increases its safety, and that compression of the limbs by bandages does likewise. Finally, Hill has shown that abdominal compression also produces resuscitation by sending the blood to the heart. On the contrary, saline transfusion, which at first glance would seem to be indicated, is useless, because the dilated blood-paths will receive all the saline for a long time before they will overflow towards the heart, for as fast as the fluid flows in they dilate.

My conclusions therefore are, that while chloroform in its general depressing power

depresses all vital functions, it is the question of blood-pressure which is most important, and therefore in the use of chloroform we should always keep the head low, precede the use of chloroform by atropine hypodermically, bandage the limbs if the case is feeble or already bloodless, and if necessary place compresses on the belly and apply them deeply by pressure if a failing circulation is developed.

The primary action of the chloroform is to depress the blood-pressure chiefly by its vaso-motor effect, secondly by its cardiac effect, and finally that while the drug does exercise a depressant effect on the respiratory centre, the failure of this centre is chiefly due to anemia. As, however, an intact respiratory centre means regular breathing, we watch this function to determine the dose of chloroform actually inhaled, and because any variation in this function, as shown in irregular breathing, means that the chloroform is disordering arterial tension. Death from chloroform, then, is usually a vaso-motor death, for an intact arterial system is as important to vital function as an intact cardiac apparatus.

---

#### *THE SUTURE-CLAMP OPERATION FOR HEMORRHOIDS.\**

BY LLEWELLYN ELIOT, M.D.,  
Washington, D. C.

It is not my intention, at this time, to discuss the various operations for the cure of hemorrhoids, but simply to call attention to an operation which I have successfully performed several times during the past year. The operation and suture clamp, so far as I am aware, originated with Dr. William Erwin, of Walter's Park, Pa., and should receive more extended recognition, as an examination of the instrument will illustrate the simplicity of the procedure.

The clamp consists of two arms bent at a right-angle at the lower end; this bent portion, which is about one and a half inches long, is provided with a shoulder one-fourth of an inch high and perforated by five small openings; the shafts above the angle are pivoted and serrated to receive a ring which regulates compression and bleeding.

To do this operation the patient is prepared by having the bowel well flushed; the legs are held with a leg-holder; the sphincter is well dilated; the hemorrhoid seized with a

---

\* Read before the Medical Society of the District of Columbia, Oct. 14, 1896.

forceps and well drawn down; the clamp is then applied as near the base of the hemorrhoid as possible, and the ring slipped along the serrations until we have a sufficient amount of compression to control hemorrhage. With a needle threaded with silk or catgut the hemorrhoid is pierced through the needle holes of the clamp. When the sutures are placed, the hemorrhoid is cut off with either knife or scissors, the sutures tied and the clamp removed; the stump is dressed with either aristol, acetanilid, iodoform, or other antiseptic material, and returned to the

do under any other operation, on account of the troublesome hemorrhage attending the use of the clamp and cautery, the incision, or the Whitehead, or the excessive sloughing which would have attended the injection method. In every case the patient has been discharged before the end of the second week, and has remained cured, if the expiration of a year without return may be regarded as a cure. There is no effort made to control the action of the bowels after the third day, when they may be allowed to move. The diet is restricted for the first few days to

Suture-clamp operation for hemorrhoids.

bowel should it not return of itself; gauze, absorbent cotton, and a T bandage complete the operation. When the hemorrhoid is longer—that is to say, has a base broader than the blade of the clamp is long—the hemorrhoid must be removed in sections, one section being completed to the tying of the last stitch, before the second section is attacked. The reason for leaving the last stitch incomplete is, that one may have a certain amount of control of the remaining part, and then again the clamp can be placed more satisfactorily. It is surprising to see what a small amount of blood is lost in this procedure; and if the sphincter has been well dilated there is a comparative absence of pain following the operation. Convalescence is usually very rapid; there is but a short detention from business, the sutures being removed on the fifth or sixth day, when the wound is nearly healed. Should the stumps remain large, a few applications of a mildly astringent solution of alum or tannic acid will contract them and cause them to disappear.

Chloroform must be administered to perform this properly, as well as any other operation about the rectum.

No case histories are cited here, but I have removed by this operation seven hemorrhoids at a sitting, when the anus resembled a link of sausage, flanked with grapes and cherries. This was more than I would have dared to

liquids or semi-fluids; then all restriction is removed.

The advantages of this operation are: it is almost bloodless; it does not present a sloughing surface; it heals rapidly; it removes the entire hemorrhoid; and it does not affect the tonicity or the calibre of the bowel.

#### CONTRIBUTIONS TO THE PATHOLOGY AND TREATMENT OF ADHERENT PLACENTA.\*

BY BEDFORD BROWN, M.D.,  
Alexandria, Va.

Firm adhesions of the placenta to the walls of the uterus may occur at any stage of gestation. I have not infrequently seen cases in the early stages, at the third and fourth months of pregnancy; then again at the fifth and sixth months, and at full term.

*Etiology of Adherent Placenta.*—Unnatural adhesion of the placenta to the walls of the uterus must be regarded in the light of a true pathological process: this is eminently true of the condition when found in the last stage of pregnancy. In all the cases occurring in my practice at term or after the fourth month there were morbid conditions of the

\*Read before the Southern Surgical and Gynecological Association, November, 1896.

system or traumatic causes existing to account for the presence of the complication. In three cases there was present positive rheumatic diathesis; in one there was present a decided gouty diathesis; in two the subjects had constitutional syphilis; three of the cases could be accounted for by traumatism, and in only two were there unknown causes.

Out of some two hundred cases of abortion in the early months of pregnancy seen in my professional practice, some thirty were complicated with adherent placenta. In my own experience in a very considerable portion of the cases of abortion the placenta has been adherent. I could not be mistaken in this condition, as the os uteri was amply dilated and the placenta remained strongly attached, and had to be scraped away in detached portions from the seat of attachment with the inserted finger. Then again, after abortion, I found in certain cases, weeks after the expulsion of the fetus, the placenta firmly attached, well preserved, with a communicating circulation with the uterus. Cases of abortion sometimes occur in which the placenta is adherent but dies from want of circulation, and remains in its attached state. After abortion, in cases of adherent placenta, if the organ is permitted to remain, and if the placenta is connected with the uterus by a continuous circulation, it continues to live and may give rise to occasional hemorrhage, but never to sepsis. On the contrary, when the adherent placenta dies and remains in utero a long train of evil consequences arise—repeated hemorrhage, sepsis, septicemia, fever, and local septic inflammation in the pelvis, as endometritis or pelvic peritonitis.

I am convinced that adherent placenta will be found in a considerable portion of the cases of abortion—many more than is generally thought.

In the cases of adherent placenta of syphilitic origin coming under my care, the abortion has taken place about the fifth month of gestation. In these cases the fetus was dead. In the cases of adherent placenta arising from the rheumatic and gouty diathesis, gestation went on to full term; in those arising from traumatism, the miscarriage occurred some two or three weeks after the injury. In two of these cases the injury was caused by blows on the abdomen; in another, by a fall on the abdomen; in all, there was pain and soreness over the location of the injury sufficient to excite suspicion of local peritonitis, and lasting for some days. The supposition was that inflammatory action was

set up by the injury in the uterine tissue at the seat of the placental attachment. One of these females had complete adherent placenta in three consecutive labors, at intervals of about two years. This patient had a remarkable tendency to acute inflammatory rheumatism. During her pregnancies she invariably had two or more attacks of acute articular rheumatism, but during the period of lactation was free from rheumatic attacks.

In these cases, whatever the primary or remote cause may be, the immediate cause of adhesion is probably inflammatory action resulting in fibrinous exudation and adhesion of the placenta to the walls of the uterus.

The character of the adhesion differs materially in the different cases: in some it is exceedingly strong and firm; in others the medium of adhesion is not difficult to overcome. I have found the firmest adhesions in the rheumatic cases: in all three of these cases the adhesion was so strong and firm that the placental tissue seemed to be a part of the uterine walls, and it was with the greatest difficulty that it could be removed and then only by scraping with the finger-nail, disintegrating the placenta in detached pieces and then scraping the uterine walls thoroughly. In some the placenta could be pulled off with the finger *en masse*; this was particularly the case with the gouty and syphilitic. In the first rheumatic case terrible sepsis, septic inflammation and septic fever followed, caused by a very small portion of dead placenta left in attachment: in the two other cases of rheumatic adhesion there were septic fevers, but of a modified type, and in the last one it only continued for a few days.

In all the cases there were slight septic manifestations, but they were easily controlled. It is very remarkable what a small portion of dead animal tissue undergoing the process of putrefaction will produce septic poisoning if left in the uterus. I have seen a portion of putrid, fetid placenta not larger than the end of the finger cause alarming sepsis, and have seen a portion of putrid membrane not larger than a silver dollar cause severe chill and a high grade of septic fever. I have again seen a decomposing clot retained in the uterus give rise to decided symptoms of sepsis. This teaches us the important lesson that we cannot be too careful in clearing the uterus of every particle of dead animal matter.

In my experience the question of sepsis in cases of adherent placenta depends almost entirely on whether a portion is left adherent

to the walls of the uterus. If even a small particle of placenta is left adherent and undergoes putrefaction, sepsis will surely follow: if the particle is very small the septic fever may not be of a violent character, but there will be more or less septic fever. But even in the case of a fetid portion remaining in utero and producing sepsis, this septicemia may be greatly modified by the action of antiseptic intra-vaginal douches. A dead piece of placenta in utero subjected to a temperature of  $100^{\circ}$  is one of the most offensive, stinking, infectious portions of animal matter I know of. I have known a portion of putrid placenta not larger than a marble when expelled from the uterus render a room horribly offensive. These small particles, often left after the removal of the mass, which are sure to become a source of trouble, can be disinfected, deodorized and embalmed so as to render them innocuous.

In all the cases followed by sepsis in my practice the attachment of the placenta was very firm and close, necessitating the removal of the placenta in detached portions after being broken up, when doubtless small portions were inadvertently left, though the walls of the uterus were carefully scraped with the finger-nails. In those cases where the attachment was such that the entire organ in mass could be pulled off there was no sepsis.

*Method of Removing the Placenta.*—As a preliminary measure to the operation of removing an adherent placenta the hands and arms of the accoucheur should be thoroughly scrubbed with carbolic soap and then bathed in a strong solution of sublimate. The vagina should be well douched with sterilized water containing bichloride in solution. The patient is now laid across the bed in the lithotomy position and placed fully under the influence of chloroform. The globe of the uterus is held down firmly by the hand of an assistant, while the operator inserts his hand up to the fundus of the uterus and gradually but cautiously pulls or scrapes off every particle of adherent placenta. This operation is really a very important one, and its success depends on its being carried out in all its details.

I performed this operation once without the aid of an anesthetic, but will never attempt it again. It is far safer for the patient and far easier for the operator, and can be completed much quicker and more thoroughly, as we have complete control of the situation. I prefer in these cases the natural

curette—the finger—to any other instrument, as the sense of touch is the very best guide and tells us what we are doing and what we should do in a manner that no metallic instrument can. If a chill and fever should occur within two or three days after the operation, we may know that we have left a small particle of dead placenta that has undergone putrefaction in the uterus and is proving a source of septic poisoning to the general system; we must be prepared to disinfect promptly this poisonous mass, no matter how small it may be, for a small portion of putrid placenta will infect a strong, healthy, robust woman and cause her death. I am so much impressed with the importance of the operation of removing an adherent placenta, and its consequences to the life of a mother, that I consider it a more momentous matter than the amputation of a limb.

CASE I.—Mrs. R., aged thirty-two; third child; had an attack of inflammatory rheumatism in the early months of her pregnancy, which continued until very near her confinement, resulting in ankylosis of the knee joint. The labor was natural. The placenta was found closely adherent to the uterus. The operation for removing the placenta was performed without the aid of an anesthetic as the patient refused to take it, and the removal was accomplished with great difficulty. It was necessary to remove the placenta in detached portions, and finally, after all was supposed to be removed, the uterine wall was scraped with the finger-nail. This case occurred twenty-seven years ago, long before the modern treatment of these cases was thought of. At that time such a thing as an intra-uterine douche was unheard of. This was the first case in which I had personal experience with a vaginal disinfectant douche in puerperal cases.

The hemorrhage during the operation was not alarming. The patient did very well until the third day, when a prolonged chill ushered in a violent fever: the pulse very soon reached 125, the temperature  $105^{\circ}$ , and the abdomen became tense and painful—indeed, all the indications of general peritonitis set in. For twelve or fifteen days the life of the patient was despaired of. During this time the pulse ranged from 130 to 135; the temperature was  $105^{\circ}$  to  $106^{\circ}$ . The typhinitis was very great.

The treatment consisted in the use of quinine in large doses; calomel and opium; turpentine stupes; a saline laxative; and vaginal douches of hot water and carbolic acid.

About the fifteenth day a small portion of intensely offensive, putrid placenta was discharged; its odor was perfectly nauseating. This particle of placenta did not exceed in size the end of the finger. From that time the pulse and temperature began to be lowered, the tympanites and abdominal pain to subside, and in four or five days my patient had passed the crisis and was beyond the danger line. Immediately after the attack of peritonitis developed the symptoms of rheumatism promptly subsided.

CASE II.—Mrs. R. This was the same woman whose history was related in Case I. Two years after the last labor she became pregnant again and in due time gave birth to another child. During this pregnancy she had two severe attacks of inflammatory rheumatism, the last continuing up to the period of labor. She again had an adherent placenta, but not so firm as before. Under the influence of an anesthetic I very carefully removed every particle of placenta and scraped the seat of its attachment. The patient had but slight fever and recovered without difficulty.

CASE III.—In her next pregnancy Mrs. R. was much afflicted with articular rheumatism and confidently predicted another case of adherent placenta, which prediction was fully realized. After her labor, which was natural, the placenta was found adherent and very carefully removed under anesthetics. No fever followed in this case, and the patient did well.

One of the most remarkable features of this phenomenal case was that every child born with an adherent placenta was profoundly idiotic and died before reaching the sixth year. This woman gave birth to three children subsequent to this without the rheumatic features and without the adherent placenta, and all of these children are well developed and fairly intelligent.

CASE IV.—Mrs. B., young woman; second child; labor natural. The placenta was found attached rather firmly, but was pulled off and removed *en masse*: it was studded with numerous deposits as large as peas throughout its tissues. This patient had suffered several attacks of gout of the toes and fingers; in the joints of the latter there were considerable deposits of urate of soda. She had quite a sharp attack of gout during her pregnancy. This case did well and was not followed by any septic symptoms.

I cannot for a moment doubt that this was a case of gouty placenta.

CASE V.—Mrs. F., aged twenty; soon after marriage contracted syphilis from her husband. When I first examined her I found a fully developed chancre on each labia, which had appeared about five weeks previous. Under treatment these chancres healed in two or three weeks. Some two or three months subsequent to this she became pregnant with her first child. At the fifth month of gestation I was called to see her. She was thin, and threatened with abortion. In due time the abortion took place without the slightest discharge of blood. This is a common feature of labors wherein the placenta is completely adherent. In this case the umbilical cord was perfectly atrophied. It was exceedingly attenuated, soft, and easily torn. The fetus was emaciated and of a pale sallow color. The placenta was found perfectly adherent in its entire circumference, and was in a diseased condition. The vagina was washed out with warm sublimate solution, and the patient placed across the bed in the lithotomy position and given an anesthetic; the hand—disinfected—was inserted into the vagina and uterus without difficulty and the diseased mass pulled off, leaving the walls of the uterus perfectly clean. I will state here that when necessary the entire hand can be inserted into the uterus at fifth month of pregnancy without the least difficulty when the patient is fully under the influence of chloroform. She recovered without an untoward symptom. During her pregnancy she had well-marked symptoms of secondary syphilis in the form of ulcerative throat and syphilitic eruption, and was treated for these symptoms. After confinement the patient was subjected to a rigid system of treatment for syphilis, with entire recovery. She subsequently gave birth to a healthy child.

CASE VI.—Mrs. K., young woman with first child; labor natural. On examination of placenta attached to one edge of the organ there was found a distinct pedicle about one inch and a quarter in length which had a torn end and evidently had been separated from an attachment to some point beyond the placenta. I thought it best to explore the uterine cavity to ascertain whether anything remained. The patient was chloroformed and a careful exploration made, with the result that a perfect cotyledon of the placenta measuring one and a half inches in diameter was found completely adherent to the uterus, but was pulled off and removed intact. The corresponding end of the pedicle

was found attached to the cotyledon. Slight hemorrhage followed the removal but no other trouble.

I have reason to believe that while these cotyledons are not frequent complications they are more frequent than is usually supposed, and that when left in the uterus they will give rise to most serious consequences in the form of puerperal sepsis.

CASE VII.—Mrs. B. during pregnancy with her third child sustained a severe fall from a considerable height, striking the abdomen about midway on the back of a heavy chair, with great force. She suffered intense pain in the region of the injury. For many days she was confined to her bed with pain and extreme tenderness over this region, accompanied by fever. At this time I apprehended general peritonitis, but the symptoms ultimately subsided without serious consequences. This accident occurred at the sixth month of pregnancy. In due time she was delivered, after a natural labor, of an ill-developed, small and delicate child. The placenta was found perfectly adherent to the walls of the uterus precisely corresponding to the seat of the injury. The adherent organ was removed in the usual way under chloroform, and subsequently the patient did well. All the indications in this case point to it as a very good example of adherent placenta from traumatic causes.

*Treatment of Adherent Placenta after Abortion during the Early Months of Pregnancy.*—After a large experience in the management of accidental abortion—amounting to some two hundred cases—in a considerable proportion of which the placenta was adherent, I have come to the conclusion that the best and safest method of removing it is to place the patient across the bed in the lithotomy position, disinfect the vagina and the physician's hand, put her under chloroform, insert the entire hand in the vagina, then the first and second fingers of the left hand in the uterus and, using the finger as a curette, remove every particle of the placenta. Then wash the uterus out with a solution containing permanganate of potash, two grammes to the ounce.

I believe this to be a better, safer and easier method than that by the steel curette, and one by which no damage can be done to the walls of the uterus.

I desire in conclusion to say a word relating to the use of ergot in cases of adherent placenta, whether after abortion in the early months of pregnancy, or at term. It can

accomplish no good whatever, and is capable of doing much harm by producing a rigid contraction of the uterus, and particularly the os uteri; in this way delaying expulsion and preventing the introduction of the fingers or hand.

#### SO-CALLED SPIDER-BITES AND THEIR TREATMENT.\*

BY DR. A. DAVIDSON,  
Los Angeles, California.

It has not infrequently happened that people have presented themselves at my office showing a small wound (usually on the hand or arm) with an inflamed areola of skin around the puncture, and complained of more or less pain at the seat of injury. To the inquiry, "What injured you?" the reply is almost invariably, "Something bit me last night—I think it was a spider;" and if by any chance they saw somewhat darkly the object causing the injury, the probabilities are they would qualify the remark by the addition of "black spider."

Of the smaller spiders popularly supposed to be poisonous we have two—*Phiddipus Johnsoni*, Peck., and *Lathrodictus mactans*, Fabr.—both quite common in Southern California. Of the larger spiders, such as the *Lycosa* and *Tarantula*, the majority are probably poisonous enough, but of these I will not speak.

Direct and conclusive proof of the poisonous nature of our smaller species is still wanting, though the fragmentary evidence available is in some particulars probably conclusive enough. The two spiders *L. mactans* and *P. Johnsoni*, in common with other members of the Aranead family, possess a poison-gland and a hollow tooth or fang through which the poison is distilled into the wound produced. The poison-gland in relation to the fang is situated somewhat as it is in the rattlesnake, the poison-sac being attached to the root of the fang by a small tube that conducts the poison down the hollow shaft. The fangs of the smaller spiders act laterally; in the tarantula and kindred species they act vertically as in the snake. When the spider strikes, the fang, which in rest is folded back, is straightened and as it strikes, the poison, if the spider so wills it, is ejected. From the nature and disposition of the muscular fibres around the poison-sac, as well as from the fact that the spiders do not always use the

\* Read before the Southern California Medical Society, Dec. 18, 1896.

poison when striking insects, the ejection of the poison is believed to be under the control of the animal, thus differing materially from the rattlesnake, where the mere closure of the jaws compresses the sac and expels the poison. A small channel penetrates the tooth, opening on the side a little way from the apex; this opening is admirably placed for the purpose of ensuring its freedom from clogging when penetrating; and the double beveling of the opening still further assists in securing its patency.

Dr. Brown of Pomona, in a paper read before the Pomona Medical Society, detailed the history of a number of cases of individuals believed to have been bitten by *L. mactans*, in all of which the history and symptoms were very much alike. The individuals were in almost every instance bitten while on the seat of the water-closet, and all cases were characterized by sudden illness following the receipt of the injury—severe pains at the seat of injury radiating to the trunk and limbs, with precordial oppression and general symptoms of collapse, nausea, perspiration, cyanosis, but no local signs. Pains lasted for weeks and recovery was slow. Dr. Brown concludes his paper by saying there seems no doubt that this animal is provided with a venom "which for its size and the quantity of its poison exceeds that of any other living thing."

All this is in marked contrast to the symptoms presented by the two cases that have come under my observation. No. 1 saw the spider as it bit his leg, and killed it; and from the account of its appearance I think it was undoubtedly a *L. mactans*. The symptoms that followed may be classed as a simple painful cellulitis such as follows: poisonous bites of other animals, but which in this instance incommoded the individual for nearly three weeks. No. 2 lay down on the ground at midday to sleep, disposing his hands across his chest. Shortly after he felt something prick him at the base of the thumb; he struck at and killed it and found it was a specimen of *L. mactans*, with which he is quite familiar. The subsequent pain was similar to that following a bee-sting, and the part rapidly swelled to above the wrist. Next day the swelling was quite as marked and the pain was still present, though slight. On the third day it began to improve, and in a week all traces of injury had disappeared.

It is possible that different results from the same animal may be explained by individual peculiarity or the rapidity of the absorption of the poison. In the event of a wound be-

ing directly inflicted on a vein it is quite conceivable that general prostration with cardiac distress and respiratory difficulty might supervene. This may in a measure explain the peculiar symptoms complained of in Dr. Brown's cases, where the injuries were inflicted on the genital regions, the vascularity and extreme sensibility of which parts may have favored the absorption of the poison and increased the nervous symptoms.

The doubt naturally arises whether the injuries in Dr. Brown's cases were inflicted by the *L. mactans* or even by a spider at all, as he gives no record of the animal having been caught. There is no doubt that if a *Lathrodectus* spider beneath the seat of a water-closet is disturbed while nesting it will attack the disturbing object nine times out of ten. During the autumn season, after spinning the cocoon that holds its eggs and protects its young, it keeps closely around or broods over it like a bird over its eggs, and is very fierce in the defense of its nest, which may in part account for the frequency of its bites and the wholesome respect the laity show towards it. The species most common in water-closets are the common *Pholcus phalangioides*, Fuesl., and if over water *Tetragnatha elongata*, Walck., both of which are supposed to be quite harmless. *Phiddipus Johnsoni*, our other reputedly poisonous species, may be found anywhere, as it is of a nomadic family, and hunts its prey after the manner of the feline race. I never saw a case of injury supposed to have been caused by this spider.

The Mexicans have a wholesome dread of "the black spider," and many say they would rather be bitten by a rattlesnake than by such an animal. Their fears, while they ought not to be wholly ignored, should not bias us against all black spiders, for some of that color are admittedly harmless enough.

It is somewhat interesting and throws a rather conflicting light on the general nature of spider-bites to review the experience of naturalists of other countries. Walckenaer (His. Nat. de Insects) says: "However violent may be the effect of the venom which a spider injects into the puncture, this venom in the largest species in France produces no effect on man." Blackwall (Linnean Society Transactions) considers all British species non-poisonous. *L. malmignatus*, Walck., of Southern Europe, according to reports published in 1843, produced painful cellulitis lymphangitis with nervous symptoms, sometimes ending in convulsions; yet Lucas has exposed himself frequently to the bite of this same

spider and felt it no more than he would the prick of a needle. The bite of the *Katipo* of New Zealand, a species of the same family, is reputed to be quite poisonous, and cases are detailed in which symptoms of depression, prostration and pain were severe, but in few if any of them was the spider seen. In this country in 1886 a case was reported from North Carolina, by an intelligent farmer, where a negro was bitten by a spider believed to have been *L. mactans*, and died fourteen hours after in convulsions.

Against the popular prejudice here and elsewhere concerning spider-bites we have arrayed the experience of almost all naturalists in favor of their harmlessness—Waldenauer, McCook, Blackwall, and others have been repeatedly bitten by supposedly injurious species without any untoward result. A dispassionate survey of the whole subject would seem to suggest that spider-bites, like bee-stings, are more or less injurious according to the individual susceptibility, but are on the whole less troublesome and serious than a bee-sting. Some people have died of collapse within half an hour after the receipt of a bee-sting, and in almost every individual they are associated with more or less local inflammation. Inflammation has been seen to pass to local gangrene in strangers in India when first exposed to mosquito bites.

This *résumé* of my knowledge of spider-bites I have thought necessary to give, though I believe it may be accepted as a fact that almost all the so-called spider-bites met with in this section are produced by no spider at all, but by an insect called the pirate bug (*Rhasahus biguttatus*, Say.). This insect is common at some periods in orchards around the city, and may be found in our streets and dwellings, being attracted along with other insects by the lights. Now and then we meet with individuals who present themselves for examination, and give a history of being bitten in the house by some animal, which they brush off and think it is a spider. Next day the injured part shows a local cellulitis with a central dark spot; around this spot there frequently appears a bullous vesicle about the size of a ten-cent piece and filled with a dark grumous fluid; a small ulcer forms underneath the vesicle, the necrotic area being generally limited to the central part, while the surrounding tissues are more or less swollen and somewhat painful. In a few days with rest and proper care the swelling subsides, and in a week all traces of the cellulitis are usually gone. In some of the cases no vesicle forms

at the point of injury, the formation probably depending on the constitutional vitality of the individual or the amount of poison introduced. An entomological friend of mine has been punctured frequently by this insect, and in a few of the instances where patients have been "stung" the insect has been captured and brought to me, so that there can be no doubt as to the animal causing the injury. Probably all so-called spider-bites inflicted on individuals in the house are caused by this pirate bug, as *L. mactans* is never found in the house, and though *Phiddipus*, being of a wandering disposition, may stray into the house, yet it is rarely found there. This solution of the "spider-bite" problem explains why the animal that inflicts the bite is rarely found. If an individual is bitten by a genuine spider the animal, even if brushed off, would readily be found, but the pirate bug if so treated would escape by flying, while the individual is guessing he must have been bitten by a spider.

This pirate bug inflicts the wound by its proboscis, and so far as I am aware does not introduce any specific poison of its own secretion into the wound. The poison introduced is probably accidental and contains the ordinary putrefactive germs that may adhere to its proboscis. The insect normally preys on aphids, flies, and black scale, and, being carnivorous in its tastes, probably also feeds on the juices of putrid animals, thus acquiring the poison with which it infects the wound.

The treatment of such wounds has been in accordance with this theory and I have therefore applied corrosive sublimate 1:500 or 1:1000 locally to the wound, keeping the necrotic part bathed in the solution. The results have been in all cases favorable; the improvement after the application of the bichloride is usually so definite as to leave no doubt in my mind of its direct beneficial influence.

#### ECZEMA UMBILICI AND ITS TREATMENT.

By J. ABBOTT CANTRELL, M.D.,

Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine; Dermatologist to the Philadelphia and Frederick Douglass Memorial Hospitals, Philadelphia.

---

Eczema of special regions demands distinct inquiry more often than does the disease when witnessed in usual or more exposed parts, and as this is especially true of eczema affecting the umbilicus or its contiguity my

remarks will be apropos at this time. Whether the part recedes or protrudes the same inquiry will be demanded on account of the numerous folds into which the disease may locate itself. When depressed beneath the general surface the condition is more likely to be unattended to until such time as the affection spreads upon the surrounding parts, because the afflicted person believes that in a short time the disease will heal of itself, but if the patient was aware what he was allowing to proceed he would immediately seek medical advice. Those persons in whom the part protrudes to some distance beyond the surrounding areas usually notice the uncomfortable symptoms long before the contiguous portions are involved and consequently seek proper intervention before the disease is allowed to progress to any alarming proportions.

Looking at the part in its natural and undiseased condition we discern a peculiar formation in its eagerness to adapt itself to circumstances. In the depressed variety usually found in those of large structure we notice a well formed concavity in which one can easily place the tip of the finger to a depth of from one quarter to one inch according to the size of the individual. The rugous elements are so arranged that one fold overlaps another in such manner as to be better able to resist contusion from without, but at the same time producing numerous sulci into which disease may creep unnoticed, and lurk until the proper time arrives for its extension. As the surrounding parts contain large collections of fatty substance the receded umbilicus is likely to be covered entirely at times during the movements of the individual, thus preventing proper access of air to the unnaturally made cavity and in a like degree retaining whatever foul air may have been introduced, thus allowing contained germs to act upon any portion of the area which may have previously been diseased. In a like manner these coverings may not allow the excreted sebum proper expulsion, but assisting it in the formation of crusts which may in themselves produce disease that in an uncleanly person may proceed for a considerable time unnoticed until disease has actually spread beyond the outer borders of the depressed area, thus complicating what may have been only the most simple of conditions. As the part is bound down by the connections beneath the derma affected in its most central portion, it can readily be seen why attention should be

continuously directed to this region for purposes of cleanliness, and so preventing the collection of any sordid or other obnoxious material which may have a tendency to produce either a simple dermatitis or a well-pronounced eczema of the part.

In those subjects where there is a protrusion rather than a depression we have a somewhat different condition confronting us, but in the main the part is arranged in a similar manner for the protection of the parts immediately beneath, and consequently shows the same rugous arrangement for self-preservation but does not show the enormous extent of sulci as found in the former variety. In the one instance we may witness the part raised only about one-sixteenth of an inch, but in the majority it is found to be protruded to one-half inch or even more above the surrounding portions of the abdomen; and this is governed by the size of the bearer, being more and more protruded as we encounter the still lesser dimensions. Naturally the part is not liable to the same amount of collections of sordid materials as the former variety, and consequently is the less likely to attacks of eczema; it should never be neglected for that reason, but should be inspected from time to time so as to prevent any superabundance of sebaceous collection in the form of crusts. One precaution that must be exercised in its behalf is to afford a certain protection from harm or bruising either from the clothing or in any other manner, thus preventing the formation of a dermatitis from which an artificial or true eczema may spring.

Now let us look for a short time upon the diseased areas, and as we notice the condition affecting the depressed umbilicus we find in the one instance that the skin has become attacked only in the sulci that are contained within the cavity, looking as it does more like an intertrigo than an eczema, but with a distinct weeping surface with some thickening and infiltration, and the slight or greater formation of crusts, all lying in the spaces between the folds, causing the exposure of numerous bleeding points upon the removal of the agglutinated material. This is rarely the extent to which the disease has progressed when it is our province to see it, but occasionally it does occur and therefore it is wise to be aware of its appearance. Usually when a case is brought to our clinics the condition has affected all of the depressed region and shows in addition to the diseased sulci an extension to even the summit of the folds, presenting a most disagreeable looking and

smelling part. It therefore presents a deeply reddened and moistened surface, with the formation of crusts in abundance, and some infiltration and thickening.

But unfortunately this is not the greatest extent to which the disease often confronts us, as many cases are brought before us wherein the condition has involved a much more extensive area sufficiently beyond the borders of the umbilicus to cause great alarm in the mind of the affected person. Besides the disease being found in the sulci and upon the summit of the various folds, it is likely to extend to one, two, or more inches beyond the borders of the most outer edge of the umbilicus; and as the condition involves the skin of this region in a manner similar to that affecting the enclosed portion of the umbilicus, it must be disagreeable in the extreme because of the great amount of discharge of a watery or serous nature, with the consequent formation of crusts which are continuously being detached and exposing a very greatly reddened and bleeding surface situated upon a thickened, infiltrated skin. The borders of the diseased area will be noticed to be fading into the surrounding healthy portion in the greater majority of cases, as is the usual manner of all forms of eczema; but in many of the cases this symptom will be entirely wanting, so that the borders will be rather abrupt, showing a distinct line of demarcation and hence complicating the diagnosis with other diseases of the skin of a much more chronic nature.

When the umbilicus extends or protrudes beyond the surrounding portions of the body the disease is rather of a milder nature when the umbilicus alone is attacked, because of the greater ease with which one may treat it; but it presents a condition similar to the former variety when the disease has spread beyond its borders, and consequently is just as annoying to the sufferer. Occasionally it may be found, when the disease has progressed far beyond the edges of the umbilicus proper, that the umbilicus has swelled to an enormous degree—possibly twice its normal size—thus complicating the condition still further, and giving much discomfort and pain, with sleepless nights.

The diseases which may at any time resemble this condition may be severally diagnosed by symptoms which each in its process presents, and individually may be differentiated by the following rules: That eczema is a moist affection, showing at times throughout its course the usual characteristics

of peculiar crusting, with a decided amount of infiltration and thickening, and a possible induration in long standing cases; that it has a tendency to fade into the surrounding parts rather than be abrupt; that the discharge is one of water or serum rather than pus; that if fissures do occur they have a tendency to self-healing; and its inherent tendency to superficial extension.

From psoriasis it may be differentiated because of its more acute nature; its tendency to moisture-crusting rather than scaling; its limitation to one portion of the body; and the intense itching.

From syphilis it may be recognized by the discharge of a serous rather than a purulent liquid; by a disagreeable odor rather than a foul-smelling stench; from the fact that syphilis is more likely to be confined to the depression, and to surround the edges by a serpiginous crawl rather than a diffuse extension; and by the peculiar color of the crust, which in syphilis is of a dark-brown color, and in eczema of a reddish blood-like character.

Pediculosis shows also distinguishing features in the fact that the lesions are more prone to be isolated and to be hemorrhagic puncta rather than a diffuse infiltration; to show the deposit of ova upon the surrounding hairs; and the possible appearance of dead or living pediculi.

In scabies the lesions do not limit themselves to this region, but may be witnessed elsewhere; but should we find lesions in this portion they would show their characteristic summit to the burrow, the peculiar tortuous outline, and the complication of vesicles or pustules with discrete crusting rather than a conglomerate mass of agglutinated material.

The treatment of this condition is generally confined in text-books to a few short lines, but unfortunately even these are not conclusive enough to give one more than a vague opinion as to what is the best plan of treatment, and consequently the condition, unless it should happen to fall into the hands of a dermatologist, is more likely to spread than to be checked in its career. But should one take into consideration the character of the condition, empirical measures may not be found amiss. First of all we have an inflammatory disease in which we may be confronted by some edema and exudation, with the tendency to the formation of crusts; its fading border, with the great desire to bleed upon the slightest provocation; and the intense itching which always accompanies the

condition. These latter symptoms may alone give one a cue as to what form of treatment is demanded, and after thinking one certainly can see that astringents are called for, with the addition of some palliative as well as an antipruritic; but oftentimes it will be seen when the condition has arrived at the chronic stage, and where the inflammation is more of a subacute character or rather quiescent, that some form of stimulant may be required first to present a favorable surface for the reduction of inflammation.

When the disease extends beyond the borders of the umbilicus we have recourse to astringent remedies in the acute or moist varieties, and of these we may find beneficial effects following the application of either calomel or acetanilid in the proportion of ten to forty grains to the ounce of the official zinc oxide ointment, or one-half ounce of this with an equal quantity of petrolatum or lanolin, applied twice or thrice daily to the part direct, or placed upon a linen cloth and then allowed to cover the diseased areas, being kept in position by some bandage. Should cases arise in which neither of these astringents will relieve or cure, sulphur, bismuth oxide, or one of the tarry preparations in the strength of one-half to one drachm to the ounce of one of the above excipients will often give decided relief and cure. This form differs little from any acute eczema upon other portions of the body, and like it we find those cases presenting a dried or chronic infiltrated or thickened appearance; but in the latter form it will be found necessary to advise the application of more stimulating remedies, and our choice will lie advantageously between resorcin, salicylic acid, salol, or possibly thymol in the strength of from ten to thirty grains to the ounce of an ointment base—with the exception of thymol, which may be advantageously advised in the strength of five grains to the same quantity—and placed upon the part in the most direct contact and covered with a roller. In those cases showing much swelling such lotions as a saturated solution of boric acid in water, or the black wash (three to ten grains to the ounce of lime-water), may be used with decided relief.

When the disease has been confined to the umbilical depression for some unknown time, then and then only will the disease give us much concern, and our choice of remedies will be demanded from those which will give us a favorable condition of the part to use curative drugs. All or most of the text-

books refer to the use of the application of nitrate of silver in solution, and I cannot but say that it has been judiciously chosen; but rather than confine myself to one remedy alone, knowing that one remedy often fails, I have studied the action of numerous others and find that some are at least just as effectual and often more beneficial than the silver caustic. The manner of applying the silver nitrate is in solutions of from ten to twenty grains to the ounce of oil, which retains it in contact with the diseased area for a proper time, naturally cauterizing the part to some extent; thus giving us a proper base for curative measures. But in my practice this has been found to give much pain in most of the cases, and for that reason I have looked around for remedies which would not be so likely to cause much discomfort, and have advised either resorcin or salicylic acid in many cases with good results. In applying the latter two drugs I have usually advised one or the other in the strength of forty grains to about two or three drachms of petrolatum or lanolin, which was to be kept in close touch with the affected portion for periods varying from two to three hours, when other and more curative measures may be adopted. In other cases I have received excellent results by using lactic acid in full strength, applied by means of an applicator upon the bleeding surfaces of the patch, and then following it with the application of one of the above mentioned astringents until the case was entirely cured.

#### *THE SUCCESSFUL TREATMENT OF ECZEMA OF THE EAR.\**

---

BY B. ALEXANDER RANDALL, M.A., M.D.,  
Clinical Professor of Otology in the University of Pennsylvania.

---

In whatever part of the body it appears, eczema has an unsavory reputation for the innumerable forms which it assumes and the rebelliousness of most of them to treatment. The therapeutics of the affection is endless and still oftener unsatisfactory; and it is generally conceded that the aural manifestations are probably the most obstinate. Hence a discussion of this matter may have an interest to those who see much more of its localization elsewhere; and measures fairly successful here may have value to those who rarely see it about the ear.

---

\* Read before the Section of Otology and Laryngology of the College of Physicians of Philadelphia, Dec. 1, 1896.

A group of differing affections may be ordinarily gathered under this one title when deserving separate names and consideration; and *Otitis externa diffusa* comprises several conditions generally distinguishable in causation and character; yet much in common can be seen in each of them, and it is to this rather than to any hair-splitting diagnosis that attention is here given. Otomycosis with manifest exuberant growth of *aspergillus* may seem a separate entity, for instance; but really the botanist rather than the surgeon is interested in the genus and species of the parasite, while those who regard all the eczemas as microbic in origin may truly be showing us that much of this is merely accidental. Each partisan of a theory may at least help on the successful treatment of these conditions; for he makes it clear that the parts involved ought with all possible speed to be made unfavorable hotbeds for the culture of such germs, whether pathogenic or accidental.

Yet the importance of local measures must not blind us to the influence of constitutional elements. A gouty diathesis is so common that we may pervert the old saying, "*Chacq'un a son gout*," and always make most careful inquiry as to the diet and life of the patient, and by medicine as well as regimen seek to lessen any such basis of the trouble. Without this the most perfect topical measures may prove futile or temporary. This aspect of the question should always lead us to scrutinize well the other ear, which may be thought to be unaffected; but this is a standing rule in otology. The evidences of its participation may be inconspicuous, but it is poor policy to overlook them. As to the local causes, it may be claimed that hardly any of the otorrhea cases escape some involvement of the skin surfaces, although the condition may be too secondary to merit any separate measures of treatment. When we look to statistical tables we find this group of affections set down at from five to ten per cent. of ear-affections, with wide individual variations as to its recognition. Add to these, as I think we rightly can, the cases of furuncular affections, and the proportion grows quite notable. These latter cases rarely fail to show evidence of previous itching of the meatus, in consequence of which the canal was scratched, in sleep if not in waking hours; and through the resulting abrasion was introduced the infection which inflamed the involved glands. As a prophylactic, therefore, as well as on its own account, such an eczema deserves treat-

ment more careful than might otherwise seem necessary.

Antiseptic cleansing should constitute the first measure of treatment; and it had better be a little overdone than slighted. Irritation of the lesions is to be decidedly deprecated, and the choice and employment of cleansing agents deserves a full consideration of this factor: but stripping off of crusts and films of desquamating epiderm should sometimes be pushed to the limit of the patient's endurance, when the oozing surfaces seem to cry out against such violence. When we remember that the seat of trouble is often in the deeper layers of the skin, the futility of merely smearing medicaments superficially must be evident; not to speak of the intervening crusts and scales, which are alone the recipients of the applications in some instances. The macerations, poulticings and douches sometimes employed have generally seemed to me contraindicated; and the prejudice which I early imbibed against water in eczema has grown stronger with experience. Oil may do better, as is claimed, and the rejection of the petroleum products has probably little basis: but long use of hydrogen dioxide has shown it to better meet my needs, in spite of its watery menstruum, than anything else. It is rarely irritating in itself unless maintained needlessly long in contact; its antiseptic properties may be rather feeble in the test-tube, but are more real in the tissues than those of most of its rivals; and, most important, it seems to reach the needy spot with greater certainty than other remedies. It is very striking in some cases of almost invisible lesions to mop the surface with the commercial dioxide and see the slight manipulation faintly reveal congested patches beneath the surface. A few moments more of gentle mopping, and patches of dead skin, probably loaded with microbes and septic matter, start so conspicuously into view that it is hard to believe that they lie deeply buried beneath an apparently healthy surface. Unsuspected points or areas are thus demonstrated and, partly at least, disinfected and prepared to receive the further medication. When this consists of an ointment, as in most of the mild and chronic cases, it is instructive to see how long it is before the oily base of the preparation can be made to penetrate to the snowy points of diseased tissue and, by rendering their cells transparent, cause them to fade again from view. Measures like this or like silver in marking distinctly the extent and thorough-

ness of our treatment, seem to me very valuable. This triple function of the dioxide in aiding diagnosis, securing at least partial antiseptis, and in marking the completeness of the farther treatment, is shared by no other agent at our command; and I doubt if in any of these rôles it is excelled by any rival.

The real medication which follows must be adapted to the exact condition presented. In some of the acute, severe, and erysipelalous lesions we may do well to treat it with ichthyol, pure or, generally better, in twenty-five per cent. ointment locally, while exhibiting tincture of iron chloride in full doses internally. If moist, a solution of silver nitrate, two- to ten-per-cent., may be used as freely as the extent and aggravation of the lesion seems to justify. The astringent action and the protection of the albuminoid layer more than offset the irritation produced; but it may at first be safer to treat only limited areas thus. In the dry but irritable phases, calomel ointment, five- to ten-per-cent., has served me best; in the more torpid, yellow oxide of mercury or salicylic acid, two- to five-per-cent.; and in the most latent, sub-epidermal form, resorcin in equal strength. It has seemed to matter little whether these were made up with the various forms of petrolatum, with lanolin or with one of the more elegant, non-fatty bases. I have no complaint to make against any form of grease which is free from rancidity. But in the use of any of them, the vehicle which may be said to be most potent in carrying the medicament actually to the affected cells is what is sometimes called "elbow-grease." This is a principle coming into recognition among most dermatologists now, I believe—that personal application of the means to properly prepared surfaces is the most important factor in the treatment; in no other way can the limitations of intervention be intelligently complied with, the remedy so well selected, or so thoroughly yet unirritatingly applied; and while the length of time involved may seem a decided obstacle, experience will reduce this to a minimum compatible with the best interests of the case. It is surely better to give the time on a few occasions and win notable success, than to spread it over many sittings which profit little or nothing. Home application of the remedy selected may well be attempted as an addition to the skilled treatment, and may prove a good adjuvant; but much of the non-success in dealing with such affections may be laid to the charge of mere prescribing, or of

inefficient employment by the medical man of medicaments potent for cure when really applied to the affected tissues.

In short, most of the commended local applications can be made efficacious by conscientious and painstaking use, with some care in selection, accompanied by rational internal medication for any underlying dyscrasia. But unless the practitioner uses both his hands and his head, his patient may about as well make his own choice of one of the proprietary articles so commonly advertised.

#### TREATMENT OF FRACTURES.

In an interesting paper on this subject, G. G. DAVIS, in the *Annals of Surgery* for December, 1896, reaches the following conclusions: 1. Massage and passive motion are not used to the extent that they should be in the treatment of fractures. 2. Immobility of the fractured ends favors quick union with little deformity. 3. There are some cases in which, owing either to peculiarities of the fracture or to impaired constitution of the individual, the tendency to the formation of callus is marked; motion in these tends to the formation of exuberant callus and deformity. 4. There are others in which bony union is unduly delayed; disturbance of the fractured ends in these hinders union. 5. It is wise to wait until the fractured parts are glued together, usually eight or ten days, before attempting any except the lightest massage, and any extensive passive motion after that time should be used carefully but diligently. 6. Passive motion and massage when first attempted should be of the most gentle character, and not so violent as to disturb the relation of the broken bones. 7. Marked pain and inflammatory reaction following passive motion and massage are evidences that it has been too violent. 8. The limb should receive massage and manipulation at each inspection or change of dressing, often daily. 9. In some cases it is advisable to administer such massage as is possible without removing the splints. 10. Persistent stiffness, particularly in fractures or injuries of the wrist, is often due to a rheumatoid affection locating itself in the injured region. Massage is valuable in the treatment of such a condition. 11. Massage should be given to the parts of the limb that lie beyond the seat of the fracture, to keep them in a normal condition. 12. Such dressings and methods of treatment should be adopted as will allow of the greatest use of massage and passive and active movements consistent with proper retention of the fragments.

### A WARNING.

A physician, giving the name of Dr. A. L. Perry, has been calling on physicians collecting subscriptions for the THERAPEUTIC GAZETTE and then failing to remit these subscriptions to the publisher.

All persons are therefore warned against paying him any money due for the THERAPEUTIC GAZETTE.

### THE VALUE OF THE OIL OF GAULTHERIA AND THE BEST WAY OF EMPLOYING IT IN THE TREATMENT OF RHEUMATIC AFFECTIONS.

From the time at which the salicylates were first introduced into medicine for the relief or cure of rheumatic affections, until the present day, one of the chief objections to their employment in effective doses has been the fact that they seriously disturb the digestion of the patient. To such an extent has this objection to their use been found

to exist that many physicians are loath to employ the salicylates, and when they are forced to give them, are so governed by the fear of this untoward influence that they administer doses which are insufficient to produce the therapeutic influence which is desired. The profession, therefore, is very ready to take up and employ any new method, or drug, by which they will avoid disturbing digestion, and it was thought at one time that in the oil of gaultheria, which contains over ninety per cent. of the salicylate of methyl, an efficient substitute for salicylic acid and the salicylate of sodium had been found. So far as we know the first careful clinical and physiological study which was made of the oil of gaultheria, particularly in connection with its employment in rheumatism, was that by H. C. Wood and the writer of this editorial in the latter part of 1885, their paper being published in the THERAPEUTIC GAZETTE in February, 1886.

It was found, as was expected, that the large percentage of salicylate of methyl contained in the oil of gaultheria had exercised a very positive influence for good in those cases of rheumatism which are usually benefited by other salicylates; and, further, that its physiological action was practically identical with these remedies. Further experience with the oil of gaultheria, however, while it supported the view that it exercised a beneficial influence in rheumatism, showed that it disordered the digestion quite as frequently as did the other salicylates, and for this reason it has not become particularly popular. Indeed there are some patients who, after taking both remedies, much prefer the salicylate of sodium or the acid to the oil of gaultheria. It has, however, been recognized as a fact for a number of years that the volatility of the oil of gaultheria rendered it easy of absorption by the skin and the respiratory mucous membrane. Quite ten years ago Randolph showed that, if oil of gaultheria was placed on a sponge which in turn was placed in an inhaler, in a very short time the reaction of salicyluric acid could be obtained in the urine upon the addition of perchloride of iron, proving that the drug was rapidly absorbed from the respiratory mucous membrane and rapidly eliminated. He also found that the use of the oil of gaultheria in an ointment applied externally resulted in its absorption and the appearance of a characteristic reaction in the urinary secretion.

Our attention has been called to this mat-

ter once more by the paper of Lannois and Linossier in *Lyon Médical* for September 20, 1896. These authors, after recalling the fact that they have demonstrated the absorbability of the salicylate of methyl through the skin in the early part of this year before the Academy of Medicine in Paris, record twenty-four cases of various forms of rheumatic affections which they have treated by the external application of this drug, and their results are such as to encourage them to continue this method of treatment, although it is a noteworthy fact that in the majority of their cases the conditions present were not such as are generally most favorable for the administration of the salicylates. Thus only four of the twenty-four cases suffered from acute articular rheumatism; in eleven the rheumatism was articular but subacute; in seven it was chronic and associated with deformity; and in two the rheumatism was gonorrheal. Curiously enough, they assert that in both of these last cases this treatment did good, although it is the universal experience of the profession that as gonorrheal rheumatism is septic in origin, and not due to the ordinary causes of rheumatic affections, the salicylates are perfectly useless.

The method which they have followed in the application of the oil is as follows: The part which is affected is surrounded by lint which has been moistened by the application of one or two teaspoonfuls of the oil; this is then surrounded by a sheet of gutta-percha, and the entire limb carefully wrapped in an outside bandage, which is applied in such a way as to prevent the heat of the body from vaporizing the drug and permitting it to escape into the air, while the bandage also softens the skin and in that way aids in the absorption of the remedy. Under these circumstances these clinicians claim that the pain is rapidly relieved, that the swelling decreases, and, as an evidence of the physiological action of the drug, that headache or fulness of the head, with throbbing of the ears and other characteristic symptoms of cinchonism, speedily appear; and, further, that in the course of so short a time as half an hour the salicyluric acid reaction may be obtained in the urine. In the course of eight or nine hours the greater quantity of the salicylate of methyl which has been applied to the limb is absorbed and eliminated, total elimination being accomplished in twenty-four hours and relief of the symptoms produced usually earlier than eight hours; the

temperature also falls, and the general condition of the patient markedly improves.

Locally this treatment may produce reddening of the skin, and if it is continued for some time, actual desquamation of the cuticle; but this is not painful since anesthesia is developed in much the same way as follows the application of guaiacol.

Considering the difficulty that is met with in the treatment of rheumatism, not only through the causes that we have named, but also from the fact that in many instances the disease is singularly persistent and resists all our remedial measures, we have thought that our readers would be interested in the results obtained by these French investigators.

---

#### THE TREATMENT OF INTUSSUSCEPTION BY NON-OPERATIVE MEASURES.

---

In *Mathews' Quarterly Journal of Rectal and Gastro-Intestinal Diseases* for January, 1897, there is to be found an interesting paper upon this subject by Dr. Pyncheon of Chicago, in which he discusses the treatment of intussusception by what he calls colono-enteric irrigation. He records the case of a girl of fourteen in whom he found an intussusception and to whom he gave relief by irrigation, a method which has been quite heartily recommended heretofore in the editorial columns of the THERAPEUTIC GAZETTE. Pyncheon describes a very useful home-made operating apparatus by which he placed the patient in the position most suitable for her relief under irrigation. In the centre of the room he inverted a high-back dining-room chair so that the top of the back rested upon the floor, and under the front edge of the seat he placed a boot-blackening stand with some large books thereupon in order to make a support of sufficient height to permit the back of the chair to slope at an angle of about seventy-five degrees. He next placed over the chair a bed-bolster and covered this with an old quilt folded lengthwise about six times. The patient was then quickly anesthetized and suspended over the chair face downward with her head near the floor and her thighs well secured between the legs of the inverted chair, the condition of anesthesia being kept up during the entire procedure. A fountain syringe was then filled with water heated to about 110° F., and the bag was hung up as high as the ceiling of the room would allow, although Pyncheon asserts that

he would have liked, had the patient been on a lower floor, to have lengthened the tube and to have hung the bag still higher. He also enlarged the opening in the rubber tip of the syringe so as to increase the rapidity of the flow of water into the bowel. Active massage of the belly walls was practiced. This flow of water was continued until, as Pyncheon states, his efforts were suddenly crowned with success by a violent gushing of water from the patient's mouth, when the operation was stopped.

In the conclusions of his paper Dr. Pyncheon points out that the rectal tube should be of such shape as absolutely to control the escape of water from the rectum; that no air must enter the gut; and that abdominal massage should be alternated with the onward flow of water.

Finally he states that the fall of water may vary from fifteen to thirty feet, according to the age of the patient and the stage of the trouble, providing that a lesser fall of say six feet, in alternation with massage, is not successful.

We have called attention to Dr. Pyncheon's article for two reasons: first, because we desire to emphasize the importance of intestinal irrigation in the treatment of intestinal obstruction; and, secondly, because we are forced wholly to disagree with the last conclusion at which the author has arrived. About ten years ago Dr. Nicholas Senn stated, as the result of experimental investigation, that it was possible by injecting water into the bowel under considerable pressure, to do serious damage to the peritoneal coat of the bowel, and for this reason the pressure recommended in the paper which we have quoted is far too great. There are very few intestinal walls which would stand a hydrostatic pressure of thirty feet, and a patient exposed to such a pressure would be seriously endangered. We speak of this matter advisedly, for in 1890 the editors of this journal were awarded the Fiske Fund Prize of the Rhode Island Medical Society, for an essay in which this subject was carefully discussed after a series of laboratory and statistical studies. In these studies it was found possible to pass water from the anus through the pyloric end of the stomach and out through the esophagus by a pressure not exceeding that produced by a water-bag held at from eighteen inches to two feet above the abdomen of the animal. It was further found that a greater pressure than this was capable of doing harm, and that it was not so much a

question of the degree of pressure as it was its continuance. Every one who has dealt with muscular fibre knows that the way to overcome its resistance is by gradual pressure continuously applied until the resistance is exhausted. While on the other hand, if we attempt to overcome muscular resistance by the application of great force, the spasm is apt to continue through irritation, and the patient is not benefited. The proper way, then, to use intestinal injections for the relief of intussusception is to anesthetize the patient, to place him in the position recommended by Dr. Pyncheon, and then to allow the water to trickle into the bowel so slowly that by the gradual application of its force the obstruction is overcome. We repeat that while we heartily agree with Dr. Pyncheon's recommendation as to the general plan of treatment in these cases, we must entirely disagree with him as to the height at which the water-bag should be placed.

---

#### *THE INFLUENCE OF CHLOROFORM ON THE VASO-MOTOR SYSTEM.*

---

In the report which the Editor of the *GAZETTE* submitted in the spring of 1893 to the Government of his Highness the Nizam of Hyderabad, upon the action of chloroform, and which was published in the fall of that year in the *THERAPEUTIC GAZETTE*, he emphasized his belief in the fact that in the great majority of cases the danger from chloroform lay in its powerful and primary depressing influence upon the vaso-motor centre, and urged upon the profession the recognition of the fact that an intact vaso-motor apparatus and a normal arterial pressure are as necessary to the maintenance of life as an intact cardiac mechanism. This view he has reiterated again and again in the columns of the *GAZETTE*, in his "Text-book of Practical Therapeutics," and in an article upon Anesthesia in Park's "System of Surgery," and lastly in an article in the original columns of this issue. Yet another time he has called attention to the importance of the normal vaso-motor tone in the diagnosis and treatment of disease in an article in the *THERAPEUTIC GAZETTE* during 1896, and he now once more calls attention to this fact, which he believes is still too much ignored by the profession, namely, that chloroform exercises its chief danger through its vaso-motor influence.

The reason that he has for once more

speaking of this matter is not only its importance but because of the confirmation which his views have had through the publication of an exceedingly interesting monograph by Mr. Leonard Hill, of London, in which are published the results of "An Experimental Research upon the Physiology and Pathology of the Cerebral Circulation," a research which was also embodied in the lectures which he delivered as Hunterian professor at the Royal College of Surgeons in February, 1896. After stating that all the tracings which he has ever seen taken from animals under chloroform, and particularly those taken by the Hyderabad Commission, show enormous falls of blood-pressure before respiration ceases, he points out that the failure of respiration is obviously due to the anemia of the respiratory centre which is produced by the fall of blood-pressure; and he has confirmed this view by his own experiments. He then goes on to state the fact that the primary and vital danger from chloroform is failure of cerebral circulation, which he asserts stares one in the face in every one of the tracings made by the Hyderabad Commission.

Again, he points out that respiration generally stops before the heart does because if the head is above the level of the heart the cerebral circulation will cease before the circulation in the coronary arteries; and the practical result of his studies is that abdominal compression immediately removes the effect of the vaso-motor paralysis, and that not only should compression be used, but also the abdomen as well as the limbs should be elevated and bandaged, in case of chloroform accident or where chloroform accident is feared. Neither can the injection of normal saline be of much benefit to the patient suffering from a chloroform accident, for as long as the splanchnic flood-gates are open, allowing all the blood to stagnate in the large abdominal blood-vessels, the addition of saline solutions simply increases this engorgement without materially increasing the quantity of liquid which goes to the brain. These are the reasons why so many deaths have occurred from chloroform when it was administered to the patient sitting erect. These researches also explain the well recognized clinical fact that the administration of atropine, which is our best vaso-motor stimulant, tends to prevent chloroform accidents.

We commend this research to our readers as one which cannot fail to impress them as a valuable contribution to the subject of which it treats.

#### PHARMACOPŒIAL PREPARATIONS OF DIGITALIS.

Under the above heading there appeared in the Philadelphia *Polyclinic* of January 2 an interesting article which was written at the request of the Editor of that journal, who expressed the hope that further discussion of the questions therein treated should be entered into. The readers of the *GAZETTE* have a vital interest in all matters pertaining to the activity and reliability of drugs, and the Editor at once asked a well known pharmaceutical chemist to write his views, which are appended. We therefore take the liberty of offering some opinions which are the outgrowth of several years of experience in handling digitalis preparations. We do not think we are wide of the mark in summing up the conclusions arrived at by the author of the above article as follows:

1. The tincture prepared by diluting a fluid extract is therapeutically less active than one made by the official method.
2. The infusion made by diluting the fluid extract with water is a different product from the official infusion.
3. The fluid extract of digitalis is not a rational or advisable product, because of variation in activity and because it will not contain the whole of the active principles of the drug.
4. The commercial German leaf should be replaced by the more powerful cultivated English leaf.
5. The claims of manufacturers of "so-called standardized" fluid extracts should be looked upon with suspicion.

We think that a tincture *can* be made by diluting the fluid extract, which will be equal in every respect to one made by direct percolation of the drug. This statement presupposes that the fluid extract diluted shall contain all the medicinally active constituents of the drug from which it was prepared. That such a fluid extract is easily obtainable we shall prove later.

If the fluid extract be prepared by the U. S. P. menstruum (63 per cent. (approximate) alcohol), and the diluent be the U. S. P. tincture menstruum (47½ per cent. alcohol) there will be a slight precipitation, but such precipitation will consist almost wholly of inert extractive matter; even this precipitate may be avoided by employing a diluent which contains sufficient alcohol.

If the fluid extract happens to be one prepared by some "pharmaceutical manufac-

turer" there will be found on the label a formula for preparing the tincture, which directs the use of a diluent of the *same alcoholic strength as the finished fluid extract*, and with which the latter will be almost or perfectly miscible.

The writer referred to does not lay so much stress upon the possible precipitation of active constituents as upon the supposition that "the fluid extract and tincture contain most probably all four principles,"\* but in view of the dissimilarity of menstrua and process, in *different relative proportions*.

If this supposition be correct we are laboring under a great delusion, and we think the compilers of the Pharmacopœia are at fault, because we believe that it was intended that in all instances the fluid extract and tincture of the same drug should contain the same active constituents, in different *quantity*, but not in different *relative proportions*. If this were not so the drug would not be exhausted of its principles, and the preparations would not be true fluid extracts or tinctures.

It makes no difference whether the active constituents of 1000 grammes of drug be disseminated through one pint of liquid or through ten pints, they exist in the same *relative proportions*.

The reason why a tincture menstruum is made weaker than the corresponding fluid extract menstruum is that the former makes up its lack of solvent power per cubic centimeter by a corresponding increase in volume.

The conclusion that the preparation of an infusion by diluting the fluid extract is both dishonest and inexcusable, commands our hearty endorsement; this becomes a plain case of substituting a preparation of different physiological effects from that of the one ordered.

When digitalis is extracted by an alcoholic menstruum of proper strength, *all* of the active constituents of the drug are dissolved; when the drug is extracted by warm water certain of the active principles (digitonin and digitalein) enter into solution, and the greater part of the undesirable ones (digitoxin and digitalin) are left in the marc. The great difference between the two preparations becomes at once apparent when the effects produced by their administration are compared.

We do not think fluid extract digitalis should be regarded as irrational because of variations in activity of commercial samples. All fluid extracts are open to this criticism,

and the only remedy for such variation as may be due to natural causes and to faulty manipulation is to subject the finished product to some process whereby its activity may be estimated and properly regulated. As such process is beyond the means of the average pharmacist, in the case of digitalis he may take comfort in the fact that if he applies the U. S. P. process skilfully, and assures himself that his drug is of good quality (as indicated by its physical properties and the price), he will obtain a fluid extract which will in nearly every instance satisfy his medical patrons.

If the pharmacist uses inferior drug, and the manufacturers of "50-cent" fluid extracts follow his example, it will not mend matters to discard the stronger preparation, because both will continue to use the same drug in preparing tinctures and infusions.

Neither should we discard the fluid extract because it appears impossible to make it of the full theoretical strength. As above intimated, the U. S. P. product seems to meet most demands; but if the physician desires a fluid which fully represents the drug, one in which no heat has been employed, he can easily obtain it in a "commercial product," made by a reputable manufacturing chemist, of the choicest drug, by the process of repercolation, and the activity of which has been measured by physiological tests on animals.

We do not concede the advisability of discarding the commercial or "German" leaf for the specially prepared, cultivated English drug. The best grade of fluid extracts on the market are powerful enough; and any advantage, if there would be any, gained by employing the cultivated leaf would hardly offset the increase in cost of crude material. If it were desirable to employ the most powerful drug we should specify the *Digitalis ferruginea*, which is said by Goldenburg to possess ten times the activity of the *D. purpurea*. The British Pharmacopœia specifies "leaves of *Digitalis purpurea* gathered from the wild plant of the second year's growth."

We suggest that the proper remedy lies in exercising more care in selecting a prime quality of commercial drug.

Manufacturers usually confine their claims of assay to a statement that the fluid extract contains a certain percentage of "extractive." This *standard* is of value only in that it insures the thorough extraction of the drug employed.

The active constituents of digitalis are glucosides, which are of such delicate con-

\*Digitalin, Digitoxin, Digitonin and Digitalein.

stitution that they cannot be extracted and estimated by chemical means such as are ordinarily employed in standardizing toxic drugs. There is a method by which the preparation of this drug can be valued and consequently adjusted, viz., to test them *physiologically,—to make their action as developed in animals, when administered in proper proportions, the measure by which to compare them with standard samples applied in like manner.*

Such testing is expensive and requires skilled operators, but the cost sinks into insignificance when we consider the importance of positive assurance as to the activity of the product.

To recapitulate, we think that:

The fluid extract of digitalis, skilfully made by U. S. P. directions, using good drug, is powerful enough for all practical purposes.

By the employment of prime commercial drug, the repercolation process, and testing by physiological means, a fluid extract is produced which is beyond criticism.

The substitution of expensive cultivated drug for the commercial wild-grown article is unnecessary provided due care be exercised in selecting the latter.

As some pharmacists and some manufacturers of pharmaceuticals habitually employ the cheapest drugs the market affords for the manufacture of fluid extracts, they would employ the same drug for the preparation of tinctures, were the more concentrated fluids abolished.

As far as we know, there is only one reliable method of determining the activity of this drug, or its preparations, viz., physiological testing.

The preparation of infusion from fluid extract is irrational and unjustifiable.

A tincture may be prepared from the fluid extract equal in every respect to that made by the official process, provided the fluid extract is of full strength, and provided the diluent contains sufficient alcohol.

#### *SYPHILIS OF THE KIDNEYS AND ITS TREATMENT.*

Until recent times it has been a commonly accepted belief in the profession that symptoms and signs of nephritis occurring during the course of syphilis are due rather to the medicines taken for the cure of the constitutional disorder, particularly mercury, than to the direct or remote effects of the syphilitic virus. This teaching probably dates from Rayer. In the last few years the journals

have contained many reports of renal involvement occurring in the course of syphilis apparently quite independent of mercurial treatment, and it is deemed established beyond controversy that the kidneys may be attacked both in the secondary and tertiary stages of the disease.

The frequency with which such involvement occurs has, however, by no means been determined, and the writings of those who have devoted most time and attention to this subject throw little light on this matter, since their conclusions vary widely.

Geraud reports albuminuria in twenty-one out of forty-six cases of syphilis, all in the primary; eight in the secondary; and two in the tertiary stage. Antisyphilitic treatment caused disappearance of the albumen. Harrison states that albuminuria occurs in from three to eight per cent. of all cases of secondary syphilis. Peterson holds that the kidney is affected during the secondary stage in four per cent. of cases. Wagner found sixty-three cases of syphilitic nephritis in 9000 autopsies. It is thus evident that no reliable estimate can as yet be made as to the frequency of renal involvement.

The symptomatology is, however, clearly understood. Early secondary syphilis of the kidney develops usually about two or three months after a chancre, the first symptom often being edema or unusual frequency of urination. Associated with this there may be headache and general digestive disturbances. The urine on examination shows albumen, blood, and epithelial, and hyaline and granular casts. Under treatment resolution is prompt; without treatment the acute nephritis is likely to become chronic.

The pathological changes are those characteristic of acute nephritis. The affection seems to be vacillating, and in its course closely resembles scarlatinal nephritis.

The late nephritic lesions are characterized by symptoms absolutely like those of chronic nephritis. Pathologically the kidneys are found to show amyloid degeneration, interstitial inflammation, and the development of gummata; these various changes are often associated. The amyloid change seems to be the most common one.

Welander (*Archiv für Dermatologie und Syphilis*, band xxxvii, heft 3), after an exhaustive study of the question concludes, in regard to nephritis of secondary syphilis, that although a slight specific albuminuria may occur with the outbreak of secondary syphilis or during recurrences in this period, this

is rare. It is very rare to find an albuminuria demonstrable to nitric acid, and it is extremely doubtful whether this is really a symptom of parenchymatous nephritis. As to the later periods of syphilis, occasionally there develops an interstitial nephritis, under such circumstances that causal relation between it and the specific constitutional disease is probable.

In the later period of the disease there occurs in exceptional cases an afebrile kidney affection characterized by a dirty-brown turbid urine containing a slight amount of albumen, blood, and epithelial cylinders and a large quantity of detritus. This affection of the kidney occurs when gummata are breaking down in other portions of the body, and diminishes and disappears under specific treatment, together with the other tertiary symptoms. It is probable that it is due to breaking-down gummata in the kidney.

Mercurial treatment, especially when it is pushed, causes cylindruria, at times albuminuria, which may be slight or severe according to the idiosyncrasy of the patient. The absence of cylinders and albumen in the urine does not show failure to absorb mercury. It is only by examination of the urine and the feces for mercury that the amount which is absorbed can be determined. The cylindruria and albuminuria caused by mercury are transitory and do not predispose to subsequent kidney affections.

When nephritis has developed, especially the parenchymatous or the interstitial variety of the disease, mercury must be given cautiously; during the course of nephritis mercury is eliminated largely through the feces, at times abundantly through the kidneys, but always to a minimal extent through the saliva.

The prognosis of nephritis occurring during the secondary period of the disease is nearly always favorable. Tertiary nephritis, if of a gummatus type, yields as promptly to specific treatment as do gummata in other parts of the body. When degeneration has proceeded to complete destruction of secreting substance there can be no restoration of tissue, and specific treatment avails only in preventing further extension of trouble.

The communication of Welanders again raises doubts in regard to therapeutics which seemed in a fair way to be cleared by recent records of renal syphilosis. His conclusions, based on a thorough study of the matter, seem to show that nephritis due to secondary syphilis is rarer than that occasioned by full

doses of mercury. The important lesson to be drawn from the study is that examinations of the urine should always be practiced in cases of syphilis; that when albuminuria and cylindruria are observed the practitioner should carefully consider as to whether this is not due to drugs rather than to the disease for which the medicine is administered; that toxic effects occur readily when the kidneys are crippled, and hence mercury must be administered with extreme caution. It seems scarcely necessary to state that in addition to specific treatment cases of syphilitic nephritis should receive the hygienic and hydrotherapeutic and medicinal care appropriate to inflammation of the kidneys when it is due to other causes.

---

## Reports on Therapeutic Progress

---

### EXPERIMENTAL RESEARCH INTO THE ACTION OF *VIBURNUM PRUNIFOLIUM* (BLACK HAW).

SHENNAN contributes the results of a literary and experimental study of this drug to the *Edinburgh Medical Journal* for November, 1896. He concludes that in habitual abortion not caused by syphilitic infection or by fatty placenta, undoubtedly good results seem to follow the use of *Viburnum prunifolium*. In threatening abortion, whatever the cause, and at whatever period of gestation, if the case is got soon enough, it seems to be very successful. In dysmenorrhea, functional, spasmodic, ovarian, or attended with menorrhagia, it often cures; if there is flexion or stenosis it gives great relief, though of course it cannot cure. In the menorrhagias and metrorrhagia of the menopause and in the nervous disorders of that time it is very beneficial. After-pains are so readily relieved by it that some (e.g., Auvard) consider that its use is dangerous unless all clots are cleared out of the uterus previously. It may be used in the diagnosis of false pains, speedily relieving them. It is also used with success in colicky diarrhea and in dysentery. Some even claim that it has a curative effect on cramps of voluntary muscles.

In his experimental tests he found that in mammals, warm-blooded animals, owing to the difficulty of giving a large enough dose hypodermically, there is no marked effect, except drowsiness and some lessening of motor power. If the substance be introduced into the heart directly, there is rapid lowering of blood-pressure to about one-half the nor-

mal, with slow return to near the normal as the drug is eliminated.

Although too much reliance must not be placed on experimental results in cold-blooded animals, including man, we may be allowed to take something from these results and use them as probably applicable. Thus, there is probably some diminution of reflex irritability, a quieting effect on involuntary muscle, possibly some lowering of blood-pressure—which even though small, might afford relief in congested conditions. Then—a very important point—there is the effect of the valerianic or viburnic acid in neurotic and hysterical conditions.

In the Pharmacopœia there are many drugs capable of bringing about all these desired effects. Why, then, use *Viburnum prunifolium*? Opium is one of our sheet-anchors, but then there are dangers and inconveniences attending its use: the patient may acquire the opium habit; the constipation caused by it is very troublesome, and it is very toxic. Viburnum has similar good effects, though not so powerful; it is a good form in which to administer valerianic acid; its effect upon unstriated muscle, though not so great as that of opium, gives the relief necessary; and it has scarcely any effect in causing constipation.

Toxic effects have only been noticed with very considerable doses. Herrick has seen disturbance of vision, dryness of mouth, headaches; and Wilson has observed similar conditions, but these followed doses larger than are usually administered.

#### NOTES ON THE EVOLUTION OF TREATMENT OF UTERINE FIBROIDS:

In a paper contributed by JOHN WALLACE to the *British Medical Journal* of October 31, 1896, the writer lays down the following propositions in connection with this subject:

Uterine fibroids had a trivial mortality compared with ovarian tumors in the times when both were left alone, or tapping only was resorted to. Death was almost inviolable in the one, and rare in the other.

The same law holds now, but ovariectomy has stepped in and the mortality has been reduced by over ninety per cent., while on the other hand supravaginal hysterectomy has enormously increased the mortality of uterine fibroids. What the percentage has been we shall never know, but it has been great.

Uterine fibroids are subject to degenera-

tive changes—fatty (the most frequent), myxomatous and cystic (the next frequent), sarcomatous (which probably existed from the beginning), and calcareous—the rarest of all if we except the carcinomatous, which the writer has never met.

In uncomplicated uterine fibroids, avoid all surgical interference, and trust to protecting the tumor from injury. The better the patient's health, the less the tumor grows. Deobstruents of calcium chloride, potassium, or sodium bromide, with syrupus ferri iodidi, have again and again reduced the size of large tumors. This view has been forced upon the writer by observation. The climacteric is invariably accompanied by atrophic changes, and in one instance a tumor—the largest he ever watched—reaching as high as the ensiform cartilage, became as small as a mandarin orange.

Large fibro-cystic tumors never atrophy, but their tendency is to increase in size. Extirpation is therefore the rule whenever their nature is ascertained.

Surgical interference is demanded: (a) in fibro-cystic growths; (b) in sarcomata in the early stages if possible—the longer the tumor is left, the greater the risk of recurrence; (c) in cases where the tumor permanently interferes with the action of bowel or bladder, with or without pain, or inflammation giving rise to adhesions to superincumbent and pelvic viscera; (d) when ascites is a sequela, or when, from overdistention, direct or reflex symptoms arise which imperil the cardiac function or in any way threaten the life of the patient. Small fibroids sometimes give rise to chronic peritonitis and ascites, necessitating extirpation; and necrosis of a tumor from injury or impaction necessitates immediate extirpation.

Hemorrhage alone does not demand extirpation by laparotomy. It can always be checked. The writer has never seen a case succumb to it, but if it is accompanied by pain, inability for life's work, etc., it may justify operation at the request of the patient, but it would not justify the surgeon in recommending it.

Fibroid uterine tumors may complicate pregnancy and have to be removed by vaginal hysterectomy when obstructive, or by abdominal section. They take on the increased growth of the impregnated uterus, and grow rapidly, but either the uterus overreaches and controls them, and pregnancy goes on to term, or abortion results. Although laparotomy and extirpation during

pregnancy has been successful, it is not an operation to be recommended generally.

If tumors can be removed by vaginal hysterectomy, with well marked symptoms as a justification—for if you give Nature time she often expels them—the direct operation by incision of the capsule, enucleation, and avulsion by torsion, ecraseur, or scissors, is to be speedily done. The old plans of opening the capsule by potassa fusa (Simpson and M. Duncan), and incision and waiting in expectation of expulsion by uterine contraction, have been abandoned. Failure, or septicemia, a hurried attempt at extirpation, and success uncertain—such were the results.

The abandonment of the ligature of the pedicle, and the substitution of the clamp, retarded the advance of ovariectomy for twenty years. Its reintroduction upon true surgical principles, the flushing of the abdominal cavity with abundance of warm water not even sterilized, and perfect drainage, have made ovariectomy a simple and safe operation in normal and uncomplicated cases. In hysterectomy the existence of a pedicle long enough was but rarely met with, and consequently in the early days the abdomen was often enough opened and closed and the case declared unfit for further interference. Koeberlé's ecraseur deposed the clamp where a short pedicle of the uterus permitted the wire to be tightened up and the hemorrhage controlled. But even that method proved clumsy in most instances, unfit and unsurgical, for it left a sloughing mass in contact with raw absorbing and peritoneal surfaces, and so gave rise to septicemia and death.

The pampiniform plexus, enlarged in some cases to the thickness of the wrist, the opening of which would be as immediately fatal as dividing the vena cava, has to be ligated by opening the capsule of the tumor, and detaching it so as to get the finger behind the vessels. Two ligatures are applied, and the vessels are divided between them. This is done on both sides. In a typical case the tumor occupies the whole of the plane of the pelvic brim. Taking care to avoid bladder and colon, cecum and sigmoid flexure, a circular incision is carried round the tumor, the lines of incision meeting at the place where the capsule was opened for the ligating of the vessels. Enucleation is now carried out; the uterine clamp (Dr. Wallace's) is then applied over the stump of uterus or cervix, and the tumor is cut off by a probe-pointed bistoury and so got out of the way. Any vessels are now picked up and tied, and the

parts well flushed with warm water. The intestines are held in position by an apron of antiseptic gauze, and the long abdominal incision partly closed by vulsellum forceps, etc. The broad ligaments are then brought together by catgut sutures in the middle line, right up to the abdominal incision and about an inch from its lower extremity. Thus a new Douglas' pouch is formed, and the stump of the uterus and bladder are left outside the peritoneum in a separate compartment. After flushing until the warm water comes back as pure and clear as when introduced, a glass drainage-tube is introduced into both cavities, the peritoneal and extraperitoneal, and the patient is placed in the prone position for twelve to twenty-four hours, or until the drain has nearly ceased. The ovaries may be taken or left. The principle is, not to increase the surgical extent of the operation.

An incision is made through the capsule, detachment is carried out, the pedicle of vascular supply ligated, and the tumor cut off with scissors. The pouch may be stitched to the lower end of the abdominal incision; it takes the part of the extraperitoneal compartment referred to.

When extirpation of the uterus and tumors for persistent urinary retention, pain, invalidism, or excessive hemorrhage, is to be performed, drag up the uterus and tumors from the pelvis; apply Wallace's clamp; ligate the ovarian and uterine vessels on both sides, *pari passu*, and divide each ligated portion of the broad ligament, including the vessels, before tightening up the next ligatures, one on each side—three ligatures on each side of the uterus are usually sufficient; then cut through the intraperitoneal portion of the cervix uteri, above the clamp; seize the stump with forceps, tentatively undo the uterine clamp and see that all bleeding has been controlled—if not, ligate the bleeding vessels; bring the broad ligaments together, make an extraperitoneal compartment, and flush and drain in the usual way.

Cystic ovarian tumors kill, as a matter of fact, if left alone; ninety per cent. recover after operation, and ten per cent. die.

Fibro-cystic tumors of the uterus are less frequently met with, but are equally fatal if left alone.

The true fibromyomata, uncomplicated and giving rise to no symptoms, may safely be left to the *vis medicatrix nature*, and thankful we ought to be that they form the great bulk of uterine fibroids. They take on fatty degeneration and atrophy during involution

of a large uterus after delivery; under obstruct treatment, though rarely; at the menopause, and after, invariably. Those that do not, do not belong to this class of tumors.

#### *THE TREATMENT OF OTORRHEA AND ITS IMPORTANCE.*

DENCH, one of the most progressive of modern otologists, has a paper with this title in the *Medico-Surgical Bulletin* of November 14, 1896. He first considers drainage and syringing, and asserts that while much has been written in favor of securing drainage by strips either of iodoform gauze or of some other antiseptic gauze, inserted into the canal as far as the membrana tympani, his opinion is that this procedure is not applicable in the majority of cases, and his experience has proved it to be so unsatisfactory that he no longer employs it. If these strips of gauze could be frequently changed, the measure would no doubt effect its purpose, but this is obviously impossible, either in private or hospital practice. He therefore prefers the old method of removing the discharge from the canal by the frequent use of the syringe, the irrigation being repeated as often as is necessary to keep the canal free of discharge.

Although it seems a very simple matter to syringe an ear, the operation is seldom done properly by the layman, and is not always successfully performed even by the physician. The fountain syringe is not adapted to the purpose, and either the ordinary piston syringe or soft-rubber bulb syringe should be used. As the removal of the accumulation in the canal is a purely mechanical process, a certain amount of force must be used in injecting the irrigating fluid. As the meatus is formed by two tubes, joining at an angle in both the horizontal and vertical planes, the deeper portion of the canal cannot be cleansed by a column of fluid unless these angles are obliterated and the axes of the two portions are brought into the same straight line. This is effected by drawing the auricle upward, backward, and outward, during the operation; by this manipulation the fibrous meatus is made to conform to the direction of the bony canal.

It is also important to remember that the tip of the syringe must be introduced into the meatus, instead of being held close to its mouth. Care should be taken that the force applied in expelling the fluid from the syringe does not crowd the tip of the instrument against the walls of the meatus. The portion

of the syringe introduced into the canal should be absolutely immovable, as otherwise the meatus may suffer from traumatism.

It is also to be borne in mind that in infants the bony meatus is absent, and that the inferior wall of the canal lies in contact with the superior wall. In order to convert this passage into a fibrous tube the walls must be separated by traction upon the auricle in the direction downward, backward, and outward, as in the adult.

The quantity of fluid to be used at each irrigation varies somewhat according to the character of the discharge. Usually half a pint is sufficient for the purpose of cleansing the meatus.

We are next to consider measures to secure asepsis. Given a serous or sero-mucous discharge from the meatus, no matter what its source may be, no further treatment is necessary to obtain a perfect cure than to prevent infection of this fluid as it lies in the external auditory canal. Frequent cleansing of its surface diminishes the chances of infection, but the danger is still further reduced if the cleansing fluid is antiseptic in character. It need scarcely be said that the syringe must be surgically clean, and that a separate receptacle should be used for receiving the washings, instead of allowing the return current to flow into the vessel containing the irrigating fluid. This absurd error often occurs unless it is guarded against by giving special directions.

The fluid to be used is largely a matter of choice. Personally the writer prefers an aqueous solution of bichloride of mercury, 1 to 3000 or 1 to 5000. The fluid should be warm, but not hot, and the comfort of the patient is the best guide to indicate the correct temperature. Many other antiseptic solutions are, no doubt, as good as the one mentioned. Peroxide of hydrogen in these cases is, however, objectionable, although it is highly recommended by many authorities. The mixing of a solution of peroxide of hydrogen with a purulent secretion is followed by the evolution of considerable gas. The mere ocular demonstration of the activity of this agent, by means of the bubbles of gas which are seen to rise to the surface of the fluid as soon as the injection is made, in no way establishes its germicidal properties. The sudden liberation of a large volume of gas in the middle ear, where drainage is imperfect, is not free from danger, and for this reason the agent is contraindicated in these cases. Another objection is the irrita-

tion of the canal which the protracted use of the substance causes.

After cleansing the canal in the manner described, it should be maintained in as aseptic a condition as possible until the next irrigation. For this purpose each irrigation is followed by the instillation of a few drops of a dilute alcoholic solution of the bichloride of mercury, of a strength of 1 to 3000, the following mixture being the one the author usually employs:

- ℞ Bichloride of mercury, 1 part;  
Water, 1000 parts;  
Alcohol, 2000 parts.

Under the use of these measures a serous or sero-mucous discharge will ordinarily cease, whether it be the result of aspergillus of the canal or of an acute catarrhal otitis media, either in a case in which the membrana tympani was intact before the acute attack, or when this structure has been partially destroyed by a previous purulent inflammation. In other words, prevent infection from without, and recovery is prompt.

If the medical attendant is familiar with the use of the head-mirror, it is, of course, wise to dry the ear carefully at least once daily by means of cotton pledgets, and to apply the alcoholic solution, above mentioned, to the walls of the canal and to the membrana tympani by means of the cotton-tipped applicator. If the membrana tympani is largely destroyed, the same application should be made to the internal tympanic wall. It is hardly necessary to say that, in making such applications, the surgeon's fingers should be carefully cleansed, and that all instruments introduced into the meatus must be in an aseptic condition. It should also be remembered that under no circumstances is the canal to be occluded with cotton: the pledget soon becomes saturated with the discharge, and infection of the contiguous walls of the canal easily occurs. Powders should not be introduced into the canal to check an otorrhea; when mixed with the secretion they form hard masses which may firmly occlude the channel and prevent free drainage. The same measures should be applied in cases of purulent otorrhea, and will prove efficient in the case of furuncles within the meatus, preventing repeated infection of the adjacent parts of the canal.

In acute purulent otitis media the treatment suggested is the most advantageous, unless the surgeon can determine the exact local condition by speculum examination. The drainage in these cases is often imper-

fect, and free incision is necessary in order to secure relief. Until this can be done, however, the systematic irrigation of the canal, and measures for maintaining an aseptic condition of the region, are of the greatest value.

In chronic purulent otitis the same measures should also be employed. In these cases, however, drainage is often imperfect, from the retention of secretion in the middle ear by the remnants of the membrana tympani or by the various reduplications of the mucous membrane lining the tympanic cavity. Here, also, free incision is necessary to secure a perfect drainage.

Again, the products of suppuration may be confined by the development of granulation tissue within the middle ear. In order to perfectly drain the cavity, this tissue must be removed either by means of the sharp curette or by the cold-wire snare. If the inflammatory process has exhausted itself, free drainage and asepsis will effect a cure. If, however, the process is still active, or if all necrotic tissue has not been evacuated, the discharge may continue, and the suggestions regarding treatment already given will merely reduce it in quantity. The author refers particularly to cases in which the bony structures within the tympanum are carious; this process may involve the ossicular chain alone, or may extend to the bony walls of the tympanum as well.

It is to be remembered that there is no such thing as "special surgery." The same broad principles which apply to caries and necrosis in other parts of the body are equally applicable to a similar condition within the middle ear. Every vestige of diseased bone must be removed before relief can be obtained. The exact procedure to be adopted must vary with the local conditions presented by individual cases. Where the caries is limited to the ossicles, and to those portions of the tympanum which can be easily reached by instruments introduced through the meatus, excision of the remnant of the ossicular chain and thorough curettement of the tympanic cavity will afford relief. Where, however, the process has extended further, and has invaded the most remote parts of the tympanic vault, and even the mastoid process, an intratympanic operation will not give relief, and some modification of the more radical procedure advised by Stacke (*Archiv. für Ohrenheilk.*, xxxi, p. 201) will be necessary.

The Stacke operation consists in detaching the auricle and fibrous meatus from the bony

structures, and drawing the soft tissues forward, so as to expose the margins of the bony canal. The mastoid antrum is then entered in the usual way, and the partition between the canal and the opening in the mastoid is broken down, and the superior wall of the bony meatus removed by means of the chisel, thus giving free access to the tympanic vault and mastoid cells. Every vestige of diseased bone is taken away, the parts being under direct ocular inspection. The posterior wall of the fibrous canal is split longitudinally, and the flaps thus formed are turned backward into the bony cavity, thus converting the external auditory meatus, the tympanum, the tympanic vault and the mastoid cells into one large cavity. The auricle is then replaced, and the incision behind the ear sutured. All parts of this space can be seen by speculum examination through the canal, and, if all diseased bone has been removed, a satisfactory result can be confidently expected.

Which operation should be selected in any individual case depends, as before stated, upon the extent of the lesion. If properly selected, the simpler operation of removal of the ossicles and curettement of the tympanum gives results which are equally as satisfactory as those obtained by the more radical operation.

#### ANTIPYRIN IN THE TREATMENT OF WHOOPING-COUGH.

In the *Gazette Hebdomadaire de Médecine et de Chirurgie* of October 22, M. LeGoff calls attention to the results obtained by many authors with this treatment. Dubousquet-Laborde employed it in 300 cases, 196 of which were cured or benefited. The average duration of the treatment was thirty-five days. The amounts given daily varied from five to fifteen grains for children up to three years of age, and from thirty to sixty grains for older children and adults. The same results were observed by Geffrier, De la Jarrige, Jasiewicz, and others. Richardière has also employed antipyrin with satisfactory results; it diminished the number of coughing attacks one-third in the majority of cases, although it never suppressed them completely; in two cases in which the patients vomited profusely it had no effect on the vomiting; he concluded, however, that antipyrin exerted a positive action, but that it was not superior to belladonna.

Whenever the renal functions are not impaired, says the author, M. Lemoine prefers

this medication to any other, as its action is surer and more rapid. To small children he gives from four to eight grains in enemata every twenty-four hours, and to children from three to six years of age and older, twenty-four grains in six doses.

Von Genser enumerated the results obtained by him in 200 cases, in which he employed two methods of treatment: Insufflations of powdered medicaments into the nasal fossæ, and antipyrin administered by the stomach. With the first method few results were obtained, and the duration of the treatment was at least forty-three days; in the second the results were more conclusive. Administered in quantities of two grains a day for each year of the child's age, antipyrin always diminished the number of coughing attacks and lessened their violence. Recovery was obtained in twenty-four days, and from this the author concluded that antipyrin shortened the duration of the disease. Many other instances are cited by M. LeGoff to demonstrate the efficacy of this treatment.

In regard to its mode of action, he says the drug is essentially a nervine, and acts as an analgesic and antispasmodic. By diminishing the irritability of the superior laryngeal nerve which, by reflex, produces the cough, it arrests the attacks of coughing and prevents serious symptoms which the intensity of the attack may cause. This action on the nervous element of the cough is the least disputed of the effects of antipyrin in whooping-cough, and was observed by M. LeGoff himself in eighteen patients, in seventeen of whom the number of attacks and their intensity diminished considerably, and in nine recovery occurred in less than twenty-five days, thus cutting short the duration of the disease very much.

In the second place, antipyrin is an antiseptic. Brouardel and Loye have shown that it is antizymotic. A five-per-cent. solution hinders the development of microbes and attenuates their virulence; its action has been manifested as well in laboratory experiments.

Concerning its action on the catarrhal element of this disease, says the author, Mouvet affirmed that if it was given in the first stage of the affection it arrested the catarrh; Soula also observed similar results. M. LeGoff himself administered antipyrin to a patient during the first stage of the disease, and not only the attacks of coughing, but the catarrh, disappeared in seven days. In his other

patients he remarked that the catarrh disappeared under the influence of this treatment more rapidly than is ordinarily the case after the cessation of the attack, and on this point he is corroborated by other observers.

M. LeGoff states that the only symptom he has observed to follow the use of antipyrin is albuminuria, which appeared in two cases; it disappeared rapidly, however, after the cessation of the use of the drug and the establishment of a milk diet. Many physiological experiments, he says, and the majority of clinical observations, demonstrate that antipyrin is eliminated well in animals and in persons with healthy kidneys; children, particularly, eliminate it easily. Cordes, Taylor, Dubousquet-Laborderie and others cite instances to show that antipyrin causes nausea, vomiting, with epigastric pains, and anorexia. It is not known, says M. LeGoff, whether these symptoms are to be imputed to any impurities in the drug, to an excess of action, or to peculiar individual susceptibilities. M. Dubousquet-Laborderie thinks the former play a certain part in giving rise to the symptoms observed. However, says M. LeGoff, the benignity of these symptoms is sufficiently assured, and we need not fear to give antipyrin even in large doses. It is prudent, however, to watch the elimination carefully, and, before giving the drug, to ascertain the condition of the renal filter.

In order to prevent any injurious action on the digestive tract, the drug is given in Vichy water as follows:

- ℞ Antipyrin, 15 grains;  
Gooseberry syrup, 300 grains;  
Vichy water, 2½ ounces.

M.

This quantity is to be taken in twenty-four hours, a dessertspoonful after each coughing attack. Besides this, M. LeGoff recommends the ingestion of milk or bouillon after each dose of the solution, as the antipyrin is thus very well tolerated.—*New York Medical Journal*, Nov. 14, 1896.

#### TREATMENT OF PERNICIOUS ANEMIA.

Our notions concerning the nature of pernicious anemia have undergone various modifications since it was recognized by Addison in 1855 and by him designated idiopathic, and its subsequent description by Biermer, in 1868, as an independent affection. A final decision cannot yet be given as to whether the disorder is dependent principally upon excessive destruction or upon deficient blood-

production, but the statement can be safely made that the affection is no longer looked upon as primary or idiopathic, and doubt may exist in some cases as to its progressive and pernicious character in the sense in which it has been customary to employ these terms.

A growing experience has taught that profound and fatal anemia may result from a variety of causes, sometimes perfectly obvious, but at other times so obscure as to escape detection at the hands of the keenest clinical observer. Sufficient evidence has accumulated to justify the conclusion that in a not inconsiderable proportion of cases the blood depravity results through the gastro-intestinal tract, perhaps in consequence of poisonous products there generated, or by infection, or from the presence of parasites of other character.

These advances in our knowledge of the etiology of the disease have not been without their influence upon a selection of the means employed in its treatment. Thus, whenever a source of hemorrhage or other wasting discharge can be discovered, the first essential step is to secure its control. When animal parasites are found to be present in the intestinal tract, their extrusion must be effected by appropriate means. When it is suspected that the condition arises in consequence of intoxication, resulting from some failure in the normal digestive and assimilative processes, measures calculated to aid gastro-intestinal digestion and disinfection will be indicated; if the intoxication be dependent upon the retention of metabolic products intended for excretion, laxatives—and especially calomel and salines—may be used with advantage.

Upon the assumption that the excessive hemolysis in pernicious anemia takes place as a result of the presence of toxic matters in the gastro-intestinal tract, Gibson was led to prescribe two-grain pills of beta-naphthol, two or three daily, in the treatment of a case of that disorder, with the happiest results.

Acting upon the same thought and adopting a suggestion of Fraser, Dieballe employed salol successfully in a similar case, in which the usual remedial agents had been employed without avail. The patient was a laborer, fifty years old, who suffered greatly from weakness, and presented a yellowish discoloration of the skin and conjunctivæ, and pallor of the lips and mucous membranes, with a reduction of the red blood-corpuscles to 1,120,000 per cubic millimeter, of the white to 2600, and of the hemoglobin to 43 per

cent. At the age of thirty-one he had had a like attack, from which he recovered in the course of six months, and again another at the age of forty-five. The red blood-corpuscles varied greatly in size and shape, and some were nucleated. Of the colorless corpuscles, 55 per cent. were polymorphous neutrophiles, 21 per cent. lymphocytes, 13 per cent. large mononuclear cells, 8.5 per cent. transitional forms, and 2.5 per cent. eosinophile cells. After arsenic, bone-marrow, iron, inhalations of oxygen, and quinine, singly and in combination, had been employed for more than four months without appreciable benefit, salol was given in doses of fifteen grains five times a day. Unpleasant symptoms arising, the frequency of administration was reduced to three times a day. The treatment was continued thus for three months, at the end of which time the red corpuscles had increased in number to 4,200,000 per cubic millimeter, the colorless corpuscles to 7000, and the hemoglobin to 60 per cent., while a gain in weight of thirty pounds had been made. Of the colorless corpuscles, the polymorphous neutrophiles were increased to 68 per cent., and the large mononuclear and transitional forms to 8 per cent., the others undergoing practically no change. The presence of eosinophile cells in about normal proportion was looked upon as indicative of maintained functional activity of the bone-marrow in the process of hemogenesis, and to this extent of favorable prognostic omen.

In cases in which the blood-forming organs are believed to be at fault, bone-marrow may serve a useful purpose. The influence which this substance is capable of exerting is still undecided, but in a disease like pernicious anemia, in which no measure can be expected to act with certainty for good, the patient should be given the advantage of every doubt, and no remedy should be neglected which may even doubtfully render a service. In the way of agents that aid in blood-making, the first place must be given to arsenic, given in doses as large as the patient will bear and for a long period of time. Iron is not capable of the same good, but may find a useful place in the treatment. Inhalations of oxygen have at times proved a valuable therapeutic adjunct.

It goes without saying that the diet should always be the most nutritious possible, special care being observed to maintain digestive integrity; while no general hygienic precaution should be neglected. Moderate and gentle exercise in the open air, within the limits of

fatigue, and exposure to sunshine, should be judiciously indulged in. Symptomatic indications must be met as they arise. Strychnine in moderate doses will almost always serve a useful purpose.

In attempting to reach a decision as to the efficacy of any plan pursued in the treatment of pernicious anemia, it is to be borne in mind that periods of transitory improvement, of varying duration, are often a part of the natural course of the disease, so that too much importance must not be attached to the favorable results that may follow the special line of medication employed. Even if such improvement continue for a long time, the conclusion must not be too hastily reached that the disease is cured.—Editorial, *Medical Record*, Nov. 14, 1896.

#### TREATMENT OF DIABETES.

At the recent French Congress of Internal Medicine (*La Sem. Méd.*, August 19) Mousse of Toulouse said he had tried antipyrin with the object of diminishing the amount of sugar, uric acid, and urea, but the diminution had only been fleeting. He had come to the conclusion that antipyrin should not be prescribed for diabetes. Beer yeast was of no use in his hands. He has tried pancreas in the fresh state in daily doses of thirty grammes, but with no better success. In his opinion the cornerstone of treatment in diabetes is diet; if drugs are used, their effect should be closely watched, as they are not infrequently hurtful.

In discussing the communication, Spillmann said he had treated two cases of wasting diabetes with injections of pancreatic juice. Each time the injections were given the sugar diminished and the weight remained stationary.

Mousse admitted that each time he had given pancreas it had seemed to him that loss of weight was retarded.—*British Medical Journal*, Sept. 26, 1896.

#### CREOSOTE AND COD-LIVER OIL IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

CHTANGUEE, in a communication to the Medical Society of Yalta during the Sixth Congress of Russian Physicians, made the following statements:

Both creosote and guaiacol are to be considered as symptomatic remedies, exercising a powerful influence in tuberculosis, not only

when it is pulmonary, but when it involves other portions of the body. It is, however, in pulmonary tuberculosis of the chronic type that they give their most signal results, being of comparatively little value in acute pulmonary tuberculosis or "galloping consumption." The tuberculous process when in the caseous condition is particularly favorable to the use of the drug, but, on the other hand, the remedy is comparatively useless in cases where the process has advanced and cavities are forming. Over tubercular laryngitis, creosote and guaiacol have very little influence, and they should never be prescribed in cases of tubercular enteritis. Should any dyspeptic symptoms arise, these drugs must be discontinued, and Chtanguée asserts that hemoptysis is a contraindication to their use. Further, he asserts that creosote and guaiacol exert no influence upon the number of tubercles contained in the sputum. Neither do they possess much influence as prophylactics. He recommends the carbonate salts of creosote and guaiacol, since they have not the disagreeable odor and taste of the more crude preparations; the dose he suggests is from thirty to sixty minims a day. Quoting the reports of those who are most enthusiastic as to the value of creosote in tuberculosis, he calls attention to the results of Notznikof and Bouchard, who claim forty-seven per cent. of cures or marked ameliorations from its employment.

In regard to cod-liver oil, he believes that its administration to cases not far advanced nearly always results in a marked gain in weight when it is given in the dose of two to five drachms a day. He believes it also exercises an antipyretic, as well as a resolvent and alterative, influence, modifying the tubercular lesion. Hot weather, however, contraindicates the employment of cod-liver oil, and it is sometimes difficult under these circumstances to keep a bottle which has been opened in fresh condition. It goes without saying that the oil has no beneficial influence so far as hemoptysis is concerned.—*La Médecine Moderne*.

#### THE USE OF HOT-AIR BATHS IN ALBUMINURIA.

In *La France Médicale* of September 4, 1896, CARRIEU calls attention once more to a very old method of treating albuminuria by hot-air baths. He does this because, considering its value, this method is too much ignored. The profuse sweating which the hot-air bath produces relieves the body of

many albuminoids, and thereby is of value to the kidney. During the administration of the bath the patient's head should be in air of ordinary temperature, and plenty of air should be given to him to breathe. The bath should last about twenty minutes, and be repeated every four days or oftener. There is usually, under the bath, a quickening of the pulse and a temperature elevation of one or two degrees. As a rule, however, the respiration is not embarrassed if the patient is given a large amount of air. The disagreeable symptoms which at times come on during earlier treatments—palpitation of the heart, headache, slight elevation of temperature, and perspiration—continue usually for an hour after the bath.

The therapeutic effects directly gained are, first, a slight and temporary diminution of the urine on the day of the bath, followed by a distinct increase in urinary secretion afterwards. The density is decreased. The albumen is also decreased in cases of both subacute and chronic nephritis, but baths are contraindicated where the kidney disease is associated with arterio-sclerosis or nervous or cutaneous lesions.

Carrieu bases his opinion upon the use of this treatment in seven cases.

#### THE TREATMENT OF BURNS IN CHILDREN.

The ordinary treatment of burns, both in adults and children, has been by Carron oil or lime-water and olive oil. In the *Journal de Médecine de Paris* of September 6, 1896, the following treatment is recommended: For superficial burns of the first degree, first a lotion of warm water which has been sterilized by boiling, then application of compresses of tarlatan folded five or six times and soaked in a solution made up as follows:

- ℞ Boric acid, 3 drachms;  
Antipyrin, 1½ drachms;  
Sterilized water, 8 ounces.

Or the following ointment may be used:

- ℞ Boric acid, 45 grains;  
Antipyrin, 15 to 30 grains;  
Vaseline, 1 ounce.

If burns of the second degree the same treatment may be used, but before it is applied the blisters should be drained by nicking them. For burns of the second degree with deeper lesions of the cuticle the part burned should be submerged in a basin containing warm water which has been sterilized by

boiling, and the temperature of this water should be gradually increased as the patient is able to stand it. An antiseptic toilet of the part with water and soap then follows, and after this it is bathed with carbolized water of two-per-cent. strength. For the relief of pain, it is well after this to wrap up the part with a compress of tarletan soaked in a mixture as follows:

- ♯ Saturated solution of boric acid, 1 pint;  
Wine of opium, 1 to 2 drachms.

Or the following ointment may be used:

- ♯ Iodoform, 15 grains;  
Antipyrin,  
Boric acid, of each, 75 grains;  
Vaselin, 2 ounces.

Should a large part of the body be burned, the child may be dipped in a bath prepared in the way just named, and during the antiseptic toilet of the burned parts general anesthesia may be produced by the use of chloroform. After this the parts should be dressed with the ointment just mentioned.

Where the burns are very severe, the part may be dressed with iodoform gauze or iodoform ointment; and if the suppuration has been severe enough to result in sloughing of the part after it has been antiseptically treated in the manner already described, it should be dressed with iodoform, charcoal, and cinchona bark, of each two ounces. It may be necessary to perform amputation after the period of shock has passed by.

#### *THE SUBCUTANEOUS INJECTION OF SULPHURIC ETHER IN THE TREAT- MENT OF HEPATIC COLIC.*

We are told by the *Journal de Médecine de Paris* of September 6, 1896, that KUMS of Antwerp has obtained excellent results from this treatment. The injections were made in the hepatic region, one at noon and the other at night, and were repeated until relief followed. Under this influence the pain decreased, the urine took on its normal color, and after a period of two months the patient was still entirely free from attacks. In another instance, in which the attacks had been unusually severe, the injections of ether repeated morning and night over a period of two days caused a rapid disappearance of the pain and of the characteristic icteroid urine.

In some instances Hoffmann's anodyne may be employed in place of ether itself. Indeed, Kums prefers it to the pure ether, as he thinks its effects are much better.

#### *THE TREATMENT OF TUBERCULOSIS BY THE SALTS OF THE BLOOD.*

STADELMANN has suggested that in a certain number of cases of tuberculosis there is a decrease in the normal saline constituents of the body, and he therefore suggests that it will be of advantage to give to patients suffering from this disease an increased quantity of saline material. Thus, he recommends that the phosphate of sodium shall be given in the dose of thirty grains three times a day, and that subcutaneous injections of six to seven grains of chloride of sodium be used. He asserts that after the treatment there is decrease in expectoration and the objective signs of disease. This treatment is in line with that of several authors, of employing artificial serum or saline fluid in the treatment of other infectious processes.—*Bulletin Générale de Thérapeutique*, Oct. 23, 1896.

#### *A DISCUSSION OF THE TREATMENT OF MENTAL AND NERVOUS DISEASES BY ANIMAL EXTRACTS.*

The *British Medical Journal* of September 26, 1896, contains a discussion, opened by ALEXANDER ROBERTSON, on this topic.

Before considering the group of therapeutic agents which is the subject of his paper, the writer names other special methods of treatment which he has used in his practice:

1. Heat and cold to the head at graduated temperatures. In some cases of insanity, recovery was at least largely due to this mode of treatment.

2. Mechanical stimulation of the brain and membranes by percussion of the skull. This has conduced to the recovery of some patients.

3. Electrization of the brain through the medulla. One electrode, passed along the floor of the nostril, rests on the cervical spine; the other is moved slowly over the convexity of the head. He has not yet used this procedure in the insane, but is now recording a case of diabetes insipidus cured under it.

4. Psychical—combined emotion and suggestion. The rapid recovery of a patient after mental shock, under this form of treatment, is referred to.

5. Hypnotism. Its power over the nervous system is illustrated by the immediate and confirmed recovery of a patient recently in the Royal Infirmary suffering from hemianesthesia, after other treatment had failed.

Observations have been made on the effects

of the following preparations: The fresh brain of the sheep; cerebrinin, an extract of the cortex; thyroid extract; Brown-Séguard testicular liquid; the thymus gland.

Myelin, or fresh sheep's brain, was given to seventeen patients. Six of them suffered from various forms of melancholia; three from chronic mania; two from paranoia; one from moderate dementia; five from organic diseases of the spinal cord. The most marked result was in the case of primary dementia.

The patient was a stout man, about forty, and was under treatment in the Royal Infirmary. His memory and intelligence were both greatly impaired, and there was some thickness of speech. He also had palsy of both legs and weakness of both arms. After five weeks of ordinary treatment he was not better, but rather worse. Three days after the myelin was begun, there was marked improvement both in mind and body. In five days he could not only stand, but walk a few steps; in nine days he walked up and down the ward; and in less than six weeks after the myelin was begun he left the hospital to resume his employment. Though nearly well, his recovery could not be said to be perfect.

Another patient, suffering from resistive melancholia of three years' standing, and who had not spoken or done any work for a year, within a week after the myelin was begun was knitting and speaking a few words occasionally. This was in January, 1893; since then she has been more or less maniacal. The author considers her incurable.

In a third patient, aged sixty, profoundly melancholic, there was recovery, and it is probable that myelin was very helpful in causing it; but this was not clear, as a little improvement was noticeable before the myelin was begun.

In a case of chronic myelitis the patient's power of walking was markedly improved for some weeks; but this change for the better was not maintained, and he gradually relapsed into his previous condition.

No distinct alteration, either for the better or the worse, was observable in any of the other patients. There was no change in their physical condition when taking the medicine, if we may so call it. Mixed with glycerin, flavored and colored with cinnamon and cochineal, it was not unpleasant to the taste. In one or two patients the larger dose of two teaspoonfuls caused sickness, but one teaspoonful was easily borne by the stomach in all cases.

Cerebrinin—practically the same agent as the last, but in a concentrated form—has been used in five cases of mental disease, two of chronic mania, and three of melancholia. The dose was generally thirty grains daily, in one case sixty. Two of the melancholic patients have distinctly improved; one is unchanged. The maniacal cases became more excited, but in one there is now greater lucidity.

Dr. Auld, a well known pathologist, now of London, in reply to the writer's inquiries, was good enough to state his impressions of the action of myelin and cerebrinin. He began a second time the use of myelin on hearing of the results of his earlier experience with it, and after some months had recourse to cerebrinin on its introduction. In his letter of June 8 last he says: "I do not know what I should exactly ascribe to the substance, but I have had two or three patients who said they were better for it; and in one case, on the medicine being stopped, the patient persisted in returning to it, and invariably declared it did much good, and still goes on with it. This patient suffered from agoraphobia, or dread of the streets and public places. Since taking the cerebrinin this has gone away. There was no organic disease in any case I had."

Thyroid extract in tablet form was given to five patients—three, dementia of years' standing; one, chronic mania. There was no mental improvement in any of them except the melancholic, but she soon relapsed. All lost weight, from  $9\frac{1}{2}$  to  $11\frac{1}{2}$  pounds, except one, a case of chronic mania, who gained 1 pound.

Brown-Séguard's testicular liquid was used in two cases, women about fifty, the one suffering from stuporous melancholia, the other from paranoia but moderately intelligent. Both were of years' standing. The contents of five tubes were introduced into the system on successive days by subcutaneous injection in one patient; seven in the other. There was no mental change whatever, nor was there any constitutional disturbance or more than trifling local effect. Apparently, the author states, he might as well have injected so much water.

Thymus-gland tablets were not used in mental disease. In cases where they were used the reduction in hemoglobin was marked—forty per cent.—and the increase of urea from three to five and one-half grains per ounce of urine in the course of seventeen days, three to six tablets daily. The patient, a boy aged

fourteen, suffered from lymphadenoma in a moderate degree. The morbid condition did not improve.

The statement by Robertson in an article published in 1893, in which he recorded his experience with myelin to that date, fairly expresses the opinion he now holds respecting the therapeutic value of these agents. It is as follows: "The impression remains on my mind that there is a constituent in the brain of the sheep, and doubtless also of other animals, which acts as a stimulus to nerve tissue—cell and fibre—in the human subject in certain morbid states of these structures." Dr. Auld's conclusion is much the same. He says: "I feel fairly confident that there is something in it, but won't commit myself more on the evidence I have. It probably, however, gives some tone to the nervous substance of the brain and cord."

Both agents have the great advantage that they do not weaken the system or seriously disturb the general health, and in using them the patients do not have to remain in bed. As many as four tablets have been given thrice daily. They will probably be found especially useful in the slighter or developing forms of mental disease and general neurasthenia. The more convenient form of tablet will probably supersede the fresh brain, as first used by the author.

His limited experience with thyroid extract does not warrant him in recording more than his general impressions regarding it. The active principle of the gland, probably akin in its nature to iodine, is clearly a powerful agent, and, apart from its special property in such conditions as myxedema and cretinism, increases greatly the metabolic changes of the body generally. This is shown by the rapid tissue-waste that usually, though not invariably, follows its use. It is evidently well fitted to disturb the existing status in insanity, and this is of the highest importance in certain forms and stages. It will probably prove useless in chronic cases where important structural alterations exist in the cerebral cortex, but it is not always easy to tell when this has happened. Its sphere of beneficial action will most likely be cases no longer quite recent, where the pathological changes in cell and fibre are not great, but might become permanent if they continued much longer. Encouraging results have already been recorded by a number of physicians. He names only Bruce and Macphail in England, Clark and Babcock in America; their experience suggests that it should be used more

especially in cases that threaten to become permanent, and, of these, in general mania or melancholia, stuporous states, puerperal and climacteric forms.

As no appreciable result of any kind followed the injection of Brown-Séquard's orchitic fluid, nothing is suggested, unless it be that it is much less active than has been alleged.

Robertson closes with the remark that in these agents, especially the thyroid and cerebral extracts, and the other special methods of treatment referred to at the outset of this paper, we have additional remedial measures, and it seems the duty of the physician in charge of the insane to have recourse to them in suitable cases. By their use, there is good reason to think, we may reduce the amount of incurable insanity.

---

#### *PUERPERAL FEVER: ITS PROPHYLAXIS AND TREATMENT.*

The *Journal of the American Medical Association* of August 1, 1896, contains an article on this topic by MONTGOMERY, of Philadelphia, who holds that the first and most important consideration in treatment is prophylaxis. With a correct knowledge of the source of danger, we are the better prepared to meet or avoid it. As the contagion in the majority of cases is conveyed by contact, scrupulous aseptic or antiseptic precautions should be preserved. The nearer the measures of the careful surgeon can be imitated and practiced, the less will be the danger to the patient. The physician in general practice who is in attendance upon sepsis or erysipelas cannot be too rigid in his measures of preparation; indeed, it is a serious question whether he should go from a patient, who is virulently infected with sepsis or erysipelas, to the lying-in chamber. During the writer's term as resident physician in the Philadelphia Hospital in 1875, he went from the surgical ward, where he was in attendance upon cases of erysipelas, to the obstetric department; no special precaution outside of cleanliness of hand and person was practiced. An epidemic of puerperal sepsis developed, in which twenty patients became seriously sick and four lost their lives.

The measures particularly to be practiced are: removal of the coat; baring of the arms to the elbows; careful washing of the hands with soap and hot water, with diligent use of the nail-brush; immersion of the hands in 1-to-

500 bichloride solution, and subsequently in alcohol. The bedding and personal clothing of the patient should be clean, the vulva should be washed with soap and hot water, the bowel emptied by an enema, and an antiseptic douche given. Digital vaginal exploration should be infrequent and only after careful disinfection of the hands. Instruments should be sterilized by boiling. Long-continued manipulation, instrumental delivery of the placenta, should be followed by antiseptic intra-uterine irrigation.

The parts should be carefully cleansed subsequent to delivery, and the uterus left firm and well contracted. Lacerations of the vagina and vulva, unless the tissues are bruised or the vitality destroyed by long-continued instrumental delivery, should be at once sutured; excoriations may be cauterized by carbolic acid. The vulva should be covered with an antiseptic pad, which should be changed as frequently as it becomes soiled. With each changing the vulva should be cleansed with an antiseptic solution. Aside from the immediate post-partum irrigation mentioned, intra-uterine or vaginal douching should not be practiced.

But physicians will reply that they have attended large numbers of confinement cases without such precautions, and no bad results have followed. This may be true. With ordinary precautions the chances are favorable, and much depends upon the condition of the patient. Not every patient, fortunately, to whom contagion is conveyed, yields to its influence. The normal secretions of the vagina are unfavorable for germ-culture. The tract is irrigated by discharge of the liquor amnii and swept clear by the passage of the fetus. Many eminent obstetricians, among whom may be named Lusk, are content to depend upon these conditions in ordinary cases; still, the preliminary douching does not seem useless.

Treatment of infection may be considered as, first, maintenance of the powers of resistance; second, production of immunity; and third, resort to surgical procedures for relief of local manifestations. This classification of treatment has reference to septic conditions. Sæpæmia or putrid intoxication is relieved by removal of the decomposing placenta, portion of membrane, or blood-clot, and subsequent irrigation and drainage.

The diagnosis is determined by the character of the lochia and the digital exploration of the uterine cavity. Decreased or absent lochia, elevation of temperature, rapid pulse,

depressed and anxious countenance, should awaken suspicion of beginning sepsis, whether accompanied or not by local tenderness. A smooth intra-uterine surface confirms the diagnosis.

The rapidity with which the vital forces are depressed contraindicates the use of depleting agents, unless it be the moderate use of purgatives to aid in elimination. Early resort should be made to tonics, stimulants, and easily assimilated and nourishing food. The most efficient stimulant will be found in strychnine, which should be given for effect, and may be administered hypodermically in doses of one-fifteenth of a grain every two or three hours where there is much depression. Opium, morphine and antipyretics should be given with great circumspection. For the control of temperature, cold sponging or the cold pack should be practiced. Pain, whenever possible, should be relieved by the ice-bag.

The natural tendency of disease germs is to develop toxins which are toxic to themselves and render the individual immune to further ravages. The better the nutrition, the more the strength is sustained, the earlier immunity will be secured. In many cases, however, the progress of infection is so rapid, the intoxication so profound, that the patient cannot survive until immunity has become established. As we cannot foretell in any individual the virulence of the infection, nor the possible powers of resistance, the use of antitoxin should be considered as indicated wherever infection is recognized. This is best given by hypodermic injection. These injections of streptococcus antitoxin should be given in doses of twenty-five cubic centimeters once daily for four days. They may be made into the cellular tissue of the abdominal wall, or into the buttocks or thighs. Of course every precaution must be practiced to render their use aseptic.

#### THE TREATMENT OF CORYZA.

In the *Journal des Praticiens* of October 17, 1896, we are told that LEMOYEZ treats coryza in the following manner: The abortive treatment, which must be introduced within the first twelve hours, may, if carelessly employed, produce a certain degree of irritation and in that manner increase the severity of the attack. In this early stage ten drops of the following mixture should be placed upon a sheet of rolled bibulous paper and the vapors be inhaled in much the same way that a cigarette is smoked. The formula is:

- ℞ Pure carbolic acid,  
Pure aqua ammonia, of each, 75 minims;  
90-per-cent. alcohol, 2½ drachms;  
Distilled water, 4 drachms.

In most cases, however, the following powder for abortive purposes is better. It must be very finely pulverized:

- ℞ Hydrochlorate of cocaine, 7 grains;  
Menthol, 4 grains;  
Salol, 75 grains;  
Boric acid, ½ ounce.

A small pinch should be drawn up into the nose every hour.

Should the attack be severe, so that this abortive treatment is likely to fail, it is well to administer a purgative with the purpose of withdrawing congestion from the head, and to produce abundant perspiration by the use of hot alcoholic beverages, liquor ammonii acetatis, or Dover's powder in doses of five to ten grains. Should the permeability of the nasal cavities be obstructed, it may be well every two to five hours to use a spray, with an atomizer, of a hot solution of cocaine in the proportion of one per cent.; or the following powder, which is antiseptic, may be employed:

- ℞ Hydrochlorate of cocaine, 7 grains;  
Menthol, 3¼ grains;  
Salicylated bismuth,  
Sugar of milk, of each, 75 grains.

Should there be reason to fear cocaine intoxication, mentholated sweet oil may be used instead in an atomizer as follows:

- ℞ Menthol, 15 grains;  
Olive oil, 5 drachms.

For the purpose of overcoming any trigeminal neuralgia, and also for the support of the system, a cachet such as follows may be given three times a day, after meals:

- ℞ Hydrochlorate of quinine, 4 grains;  
Antipyrin, 7 grains.

For the purpose of preventing reddening and excoriation of the nares, they should be anointed with borated vaselin.

In regard to the prophylactic treatment of coryza in persons who are exceedingly susceptible to attacks, it is well to remember that any intemperance in relation to alcoholic beverages increases the susceptibility to coryza, and that chronic lesions in the nose should be removed, as they maintain a tendency toward acute inflammation. Particularly is this true of adenoid vegetations in children and hypertrophic rhinitis in adults.

#### THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

Additional testimony is constantly accumulating to establish beyond a doubt the utility of antitoxin in the treatment of diphtheria. A recent contribution can be found in the report made by FURTH (*Münch. Med. Woch.*, 1896, No. 29) of 150 cases thus treated at the medical and surgical clinics of the University of Freiburg. This report is supplementary to a previous report of 100 cases treated in the same way. Of the 150 cases, diphtheria bacilli were found in 123. In the remaining 27 the diagnosis was confirmed by subsequent tracheotomy; of these, besides, 13 terminated fatally, and were examined post-mortem. Twelve cases in which diphtheria bacilli were not found, were treated with the antitoxin, but they are not included in these statistics. In 34 of the 123 cases streptococci also were found, but the examinations were made twenty hours after inoculation—at a time thus unfavorable to the development of streptococci. In the case of five children with laryngeal diphtheria, of whom three required tracheotomy and two died, diphtheria bacilli were cultivated from the pharynx, although this was free from membrane, swelling, or redness. One of these children had measles also, so that the diagnosis was a matter of considerable significance. Of the 150 cases, 122 were uncomplicated and 28 complicated. The complications included measles (16), scarlatina (5), measles and scarlatina (2), measles and typhoid fever (1), and tuberculosis (4). Among the 122 uncomplicated cases there were 12 deaths (9.8 per cent.); tracheotomy was required in 26 cases (21.3 per cent.), with 9 deaths (34.6 per cent.). Among the complicated cases there were 11 deaths (39 per cent.); tracheotomy was required in 9 cases (32 per cent.), with 6 deaths (66.6 per cent.). Of the whole number of 150 cases, death occurred in 23 (15.3 per cent.).

Notwithstanding the coincidence of epidemics of measles and scarlet fever, the mortality was lower than in any previous year. The proportion of cases requiring tracheotomy was also smaller, and the mortality among these lower. Over and above the complications the disease itself was in many instances of unusual severity. While in former periods the mortality in early life had varied from sixty to one hundred per cent., in the present collection of cases there were only three deaths among nineteen children under two years of age, although eight of these

cases required tracheotomy. The dose of the antitoxin employed was larger than previously. Of the fatal cases, two were septic, without involvement of the larynx; both of these came under observation on the fourth day of the disease, and death took place in sixteen and sixty-eight hours, respectively. In six cases death resulted from descending croup; all required tracheotomy. In two cases death was due to diffuse broncho-pneumonia, after the local process had terminated. Finally, in two of the cases death resulted from paralysis of the heart on the sixth and forty-first days of observation, respectively.—Editorial, *Medical News*, Nov. 28, 1896.

#### HYDROCEPHALIC IDIOCY.

The well known neurologist of New York, Dr. PETERSON, writes upon this topic in *New York Medical Journal* of July 25, 1896. He believes that the treatment of chronic hydrocephalus of the simple, primary kind is medical or surgical. Bourneville sums up the medical treatment which he has found successful in some instances as follows: 1. Compression (Barnard, Trousseau). 2. Revulsives (Gelis). 3. Internal administration of calomel (Gelis).

The head of the child is shaved, and a capeline bandage applied for a week. After a week's rest this is renewed, or, if any incident contraindicates this, daily friction with mercurial ointment is substituted. At the same time calomel is administered twice weekly, in  $1\frac{1}{2}$ -grain doses. Every month, for a year or more, a vesicatory is applied to the head for from fifteen to twenty hours, and, when it begins to dry, compression is again employed. In addition to this, exercise, massage of the limbs, salt baths, douches, tonics, etc., are used as required. Pedagogic treatment is important for this class of cases when cure or arrest of the disorder seems evident.

Thus far surgical procedure of any kind has not proved to be of particular value. Most patients have died as a result of operation. Possibly a more conservative method of operating may be devised in the future. Up to the present time the surgical procedures resorted to have been (1) craniectomy and drainage; (2) puncture of the lateral ventricles; (3) puncture of the fourth ventricle; (4) lumbar puncture.

Craniectomy with drainage may be excluded nowadays altogether from the category of expedients. The patient is almost

certain to die as a result of the sudden evacuation of a large amount of fluid.

Puncture of the lateral ventricles, even if carried out carefully according to Keen's method (*Medical News*, December 1, 1888) promises but little more, and had best be abandoned as a remedial measure in this class of cases.

Trephining of the occipital bone, three-fourths of an inch below the superior curved line, to the right of the middle line, with subsequent enlargement of the opening downward, and the insertion of a probe into the fourth ventricle, is an operation which was proposed by Parkin (*London Lancet*, 1893) and carried out in four cases, two of which recovered. On theoretical grounds this form of procedure seems to have much in its favor, and to deserve more extensive trial. A similar measure, successfully tried, is trephining in the region of the temple and insertion of the cannula in the subarachnoid space of the fissure of Sylvius.

Lumbar puncture—by which is meant the insertion of a drainage needle through an intervertebral space in the lumbar portion of the spinal column into the spinal cavity—has been rather extensively employed of late in a great variety of affections of the central nervous system, hydrocephalus being among them. Jacoby (*New York Medical Journal*, Dec. 28, 1895, and Jan. 4, 1896) has recently made a careful study of the subject of lumbar puncture in connection with a number of central nervous maladies. Quinke seems to have been the originator of the method (Tenth International Congress, 1891), though Wynter (*London Lancet*, 1891) proposed it about the same time. It seems to be a simple and harmless procedure, as well as a powerful means of reducing intracranial pressure. An ordinary aspirating needle (one millimeter in diameter, eight centimeters long) is aseptically employed. The space between the third and fourth lumbar vertebræ is selected, five millimeters to the right of the median line, though in children the puncture may be made directly in the median line. An anesthetic is rarely required. The needle should be pushed in from two to eight centimeters. The fluid begins to flow out in drops or in a small stream, according to the degree of intracranial pressure. The amount of fluid allowed to flow out must be gauged by the indications and conditions; Fürbringer withdrew in one case 110 cubic centimeters at one time. On removing the needle, the puncture is closed with a little

iodoform collodion and a compress with adhesive plaster. Fürbringer, Huebner and Ewald report temporary improvement in hydrocephalus after lumbar puncture, but the method is as yet too novel and has been too little used to allow of any definite conclusions as to its value in this class of cases. Several cases of recovery from hydrocephalus by means of this measure have been reported.

Operation does not preclude the employment of other means. Horizontal bandaging of the head with a wide rubber bandage after tapping, and the use of cod-liver oil and phosphorus, are certainly of considerable service and should not be neglected.

---

*THE MEDICAL TREATMENT OF TIC DOULOUREUX IN CONNECTION WITH THE QUESTION OF OPERATION.*

In an article with this title in the *British Medical Journal* of November 21, 1896, EWART states that the medicines he has employed with some success in the present cases are not claimed to be specifics nor to be suitable to all. Greater importance belongs to the method, which is based on the assumption of a constitutional factor, and on the clinical contrast between tic and the ordinary neuralgia. A merely symptomatic and sedative treatment, such as may benefit ordinary neuralgia, is powerless and only too likely to perpetuate the ailment. While ordinary neuralgia, although seldom overcome by sedatives alone, is benefited by alcohol, by iron, by strong tonics, and by a generous diet, these are precisely the agents which often aggravate tic douloureux, as though in this neuralgia the nerve reacted to some irritant quality of the juices—such, for instance, as we may assume to exist in the gouty state—rather than to their deficiency in nutritive value. The constitutional element in treatment, namely, diet and hygiene, is for this reason an indispensable adjunct to medication. In the treatment of the cases narrated, special regard was directed to the indications for sedatives, restoratives, alteratives, and tonics respectively.

Sleep being the first essential, and the basis of the entire treatment, it is necessary that the narcotic prescribed should be sufficiently strong to procure prolonged slumber. Chloral and morphine combined will usually prove effectual.

The restorative measures include mental and bodily rest and suitable alimentation. Rest in bed is indicated in all severe cases

till remedies have taken effect; and the success of the treatment may largely depend upon this means of economizing nerve energy. Alimentation is the second essential, but needs to be adapted to the irritable state which prevails at this stage. The tenderness of the mouth, and its often unhealthy state, and the feeble and faulty digestion, call for careful selection and for a gradual progression in diet; and the question here arises as to the use of nitrogenous food and of alcohol. The object of the treatment is to raise the nutrition without overloading the blood with nitrogenous waste. Thus a modified vegetarianism, including a liberal supply of the vegetable foods and a moderate amount of the nitrogenous, is generally indicated. Vegetarianism itself deserves a full trial in the worst cases before resorting to operation, and is said to have been attended with most favorable results, though Dr. Gowers refers to the opposite experience in a case where the neuralgia began coincidentally with the adoption of the vegetarian plan. Vegetable food was liberally, but not exclusively, supplied in the cases reported by Ewart; in one case, however, the patient has been for the last two years a strict vegetarian, with the exception of eggs. Alcohol is to be avoided; sufferers are well aware that the relief it affords is purely temporary, and it is regarded by the writer as decidedly harmful in promoting a liability to the attacks. While this liability prevails it should be absolutely forbidden; subsequently total abstinence is the safer course, and should be the rule in the gouty cases. Nevertheless, in enfeebled and underfed subjects, stout, or even port wine, may be allowed as a temporary help to nutrition.

Dyspepsia due to gastro-hepatic catarrh may have to be dealt with as a preliminary; and in a mild case of this kind the neuralgia may rapidly subside under treatment directed to the stomach. The state of the teeth, and of the gums also, calls for every attention, though, as regards the teeth, more than is needful has often been done before the patient comes under treatment. It is a well known characteristic of the sufferers that they ruthlessly sacrifice their sound teeth as well as those decayed, in the vain expectation of relief. But the mucous membrane may be less at fault than the chemistry of digestion and of its products; and more searching remedies, which may be broadly termed alterative, will be needed.

The alterative treatment may, in genuinely gouty cases, be specially directed to the gout,

with careful avoidance, however, of any depressing agents. In the generality of cases a modified treatment, favoring absorption as well as glandular activity (particularly that of the liver), will meet the gouty as well as the general indication. The salicylates, the benzoates, sulphur, chloride of ammonium, and taraxacum, are available, but none of them probably equals in efficacy the salts of iodine and of mercury, and particularly their combination in the proportion of twenty to thirty minims of the solution of the perchloride of mercury to six to ten grains or more of the iodide of potassium. The iodide may be tried alone, and should then be given in sufficient doses; its action seems to be promoted by the addition of tincture of iodine in doses of fifteen to thirty minims. The full measure of relief, however, was not obtained in the two cases where the drugs were administered in installments, until mercury was added to the iodides. Where the iodides alone had failed, this combination brought about a cessation of the pain. As a useful adjunct, guaiacum, a drug so highly recommended in gouty affections, was employed; flavored with syrup of orange, it formed a mixture more unsightly than unpalatable, but in private practice it is better administered separately. No anodyne was in any of the cases administered conjointly, the night draught having become unnecessary after the first two or three nights.

Reduction of vascular tension is a well known property of the drugs in question; but it is difficult to apportion the share taken in the result by this influence, and by the favorable action on glandular and general metabolism and on absorption respectively. The action of nitroglycerin, which has also been prescribed with benefit, is less doubtful, and it is not, as is that of aconite, open to the objection that it produces undesirable depression.

The tonic measures, as already indicated, are less dependent on drugs—though the vegetable tonics may be used with advantage—than on hygiene, and, above all, on muscular exercise, which has the advantage of diverting energy from the oversensitive nervous mechanisms while raising the general nutrition. Muscular work should be at first passive, and only gradually increased. Ordinary massage may be applied at an early date after the needful long sleep has been obtained, and should be gradually replaced by the "resistance movements," and in suitable cases by Swedish gymnastics. Salt baths

may be combined with this treatment, which, by diverting the circulation to the skin and muscles, would tend to relieve the nervous system. Climatic treatment may also be resorted to.

The treatment which has been sketched is complicated in its details, but simple in its general principles. The action of drugs needs to be favored by every hygienic advantage, and, above all, by a removal from home influences, which act as exciting causes. Probably no health resorts can confer advantages comparable with those gained by the poor from a stay in the hospital, which fulfils almost all the hygienic indications.

---

#### *THE TREATMENT OF ASCITES BY INJECTIONS OF OXYGEN INTO THE PERITONEUM.*

At a recent meeting of the Lyons Société Nationale de Médecine, M. TEISSIER related the case of a woman who came under his care for ascites with generalized edema. He treated her according to M. Potain's method of abdominal puncture followed by injections of oxygen into the peritoneum. At the first puncture about fourteen pints were withdrawn, but no amelioration occurred, as the liquid collected again in six days. A second puncture was then made and followed by the injection of 1300 cubic centimeters of oxygen. The operation was very well borne, and did not provoke any pain or local reaction; there was also complete absence of fever during the following days. The abdominal circumference diminished from 128 to 102 centimeters, and the edema of the lower limbs disappeared very rapidly. The oxygen was easily absorbed by the peritoneum. For some days there was some gurgling, but this disappeared at the end of eight or ten days. At the time of writing, the abdomen still measured 102 centimeters and sonorousness existed everywhere, even in the iliac fossa when the patient lay on her side. She was able to get up every day and walk in the open air. These results were obtained in three weeks.

The patient entered the hospital suffering from alcoholic cirrhosis, and after her entrance the liver increased in size and cardiac symptoms presented themselves. The diagnosis, said M. Teissier, might be open to discussion, but that was of secondary interest only; he presented the case because he had seen the grave symptoms disappear in three weeks under the influence of an injection of

1300 cubic centimeters of oxygen into the peritoneum.—*New York Medical Journal*, Aug. 1, 1896.

*A CASE OF MALARIAL HEMATURIA, WITH SUMMARY OF TREATMENT.*

In the *Alabama Medical and Surgical Age* for August, 1896, GUICE sums up his treatment of this serious condition as follows:

1. To control pain, restlessness, or other distressing symptoms, give hypodermically about a quarter of a grain of morphine, and repeat *pro re nata*, observing always that narcotism be not induced. Atropine is added to the morphine when indicated by the condition of the patient. The opiate is also vastly beneficial as a stimulant and regulator of the vaso-motor system.

2. Epsom salts should be given (particularly in the early stage) in full doses about every four hours until about six copious evacuations are obtained. Subsequently the bowels should be moved daily by the use of smaller doses of the salts. The active purgative effect produced by the magnesium sulphate is rationally one of the most important adjuncts to the treatment. The vigorous osmosis thus set up in the alimentary canal constitutes a valuable factor in relieving the congestion of the kidneys by lowering the vascular tension, and thus assists in controlling the hemorrhage. And the same osmotic action of the salts relieves the hepatic engorgement; in fact, all the organs supplied by the portal system are thus relieved or largely benefited. The purgation also tends to relieve the nausea and vomiting and otherwise to assist in placing the alimentary system in condition to retain and assimilate both food and medicine.

3. The turpentine is given early in the attack in the dose of ten drops every three or four hours, and continued till the urine is clear and the patient beyond the period of danger. It is an axiom with those best acquainted with malarial hematuria, that the oil of turpentine is by far the best remedy for the renal hemorrhage. And, aside from its hemostatic action, turpentine is a reliable diuretic, and thus renders additional service in preventing the suppression of urine. It is also a valuable vaso-motor stimulant, and thus fills another important indication, especially in the graver types of the disease.

4. The tincture of chloride of iron and solution of arsenic are given in combination, and operate to improve the condition of the

blood and tone up the failing vital forces. The arsenic also acts specifically to counteract and destroy the germ of malaria. Eight to ten drops of the iron and two to three of the arsenical preparation should be given every three to four hours, and continued until convalescence is fully established.

5. In malarial hematuria the patient cannot be considered free from disease or exempt from relapses even after he has reached the stage of advanced convalescence. In truth, he is then, in most cases, only restored to the condition of malarial cachexia, with such additional damage as may have resulted from the exacerbation which precipitated the hematuria. Unless the patient receive proper treatment at this stage, he will continue in a state of malarial cachexia or probably suffer a recurrent hematuria. In all cases, therefore, the patient should remain under the care of the medical attendant, avoid exposure and violent exercise, and have nourishing food and comfortable clothing; above all things he should continue, for not less than thirty days, such treatment as is best adapted to the cachetic condition. Guice has used with unfailling success, in such cases, a combination of iron, quinine, and arsenious acid. The formula given in the case reported is a good one. Should the patient be unable to take pills or capsules, the following combination will be found effective:

B Quininae sulphat., 3j;  
Tinct. ferri chlorid., f 3 v;  
Liq. acidi arseniosi, f 3 iss;  
Potass. chlorat., 3j;  
Syr. zingib., q. s. ad f 3 iv.

M. Sig.: Teaspoonful in water thrice daily, after meals.

The foregoing treatment will prove effective, for this stage, in almost all cases, if strictly carried out for a sufficient period. And it is only reasonable that time should be required to correct the structural lesions existing in the spleen, liver, kidneys, etc. The same is true of the profound anemia and other pathological changes in the blood which preceded and were intensified by the hematuric paroxysm. The treatment, then, should be pursued until the patient is restored to health, whether one month or twelve be required.

*ON THE TREATMENT OF BIRTH-MARKS.*

There is nothing desperate in the way of treatment that a person afflicted with a birth-mark of the face will not try, and therefore the article by ALGER in the *Medical News* of

August 22, 1896, is worthy of note by the general practitioner. As Alger says, *nævi* have been treated by caustics and acids, by the actual cautery, by pressure, by ligature, and by vaccination. The *nævus araneus* is very easily destroyed: a very hot needle or a needle dipped in carbolic acid may be plunged into the central capillary, thus destroying the whole mark in a very few seconds. But this procedure is objectionable where larger growths are concerned. They require great fortitude on the part of the patient, or the use of an anesthetic, and give considerable pain afterwards, while the destruction of tissue cannot very well be controlled. This is a very serious drawback, for we depend for our results upon the substitution of a scar for the mark, and the lighter and thinner the scar the better the cosmetic effect. For these reasons, the methods outlined above should never be employed about the uncovered parts of the body. The use of freshly prepared ethylate of sodium has been very highly recommended in vascular *nævi* that are not too large and deeply situated. It is rather painful, but after one or two applications a thin crust forms, which falls off in a few days, leaving a fairly thin scar. But unless the solution be freshly and carefully prepared, it is in effect an aqueous solution of caustic soda.

All things considered, the use of electrolysis is by far the most satisfactory means of treatment; but in order to secure good results it is necessary to have a good idea of the physical and chemical properties of the current. The appliances necessary consist of a galvanic battery of at least ten cells, or some means of regulating the street current, conducting cords, sponge electrodes, needle-holder, needles, etc. A milliampère meter is not necessary, but it is an assistance to good work. The cells should be connected zinc to carbon. The needle-holder is better without the spring for breaking the current which is generally provided. The needle may be varied in size according to the character of the work, from that of the very finest jeweler's needles to the broad flat surgical ones.

The sponge or punk electrode attached to the positive pole, thoroughly moistened with saline solution, can be continuously applied to the skin, the current being regulated through a rheostat; but the best way is to have the patient hold the sponge and complete the circuit by pressing it against some convenient part of his body. It is less pain-

ful to break the current at the positive pole, and the patient is able to partially regulate it by increasing or decreasing the pressure. The needle, attached to the negative pole, should be introduced at the margin of the growth, either perpendicular to the surface of the skin, or in a slanting direction, according to the size and depth of the *nævus*, and a current of from one to three milliampères used, according to the patient's fortitude. There is at once evolved at the negative pole, about the needle, hydrogen gas, which can be seen bubbling up, and a caustic alkali, which destroys a certain amount of tissue in proportion to the strength of the current and the depth to which the needle has penetrated. No arbitrary rule can, therefore, be laid down as to the time required, which is dictated entirely by experience. If the application is too protracted, too deep a scar results; if not sufficiently protracted, no appreciable effect is produced. The proximity of the insertions must be governed by the effect desired, which is to combine the white of the scar-tissue with the red of the *nævus* so as to produce a general effect as much like the rest of the skin as possible. The punctures should not be closer together than one-sixteenth of an inch. If the mark is large, work can be facilitated by using a group of needles.

In the large angiomaticous *nævi* it is much harder to get a perfect cosmetic effect, for the scarring is apt to be deeper and more irregular, and on the whole a different procedure is advisable. The negative pole should be attached to the sponge this time, and in place of the steel needle a coarser one, of either copper, zinc, or silver, attached to the other pole. This should be introduced deeply into the mass, and a current of from three to five milliampères used, as positive electrolysis is less painful than negative. About the needles oxygen can be seen bubbling up; chlorine and an acid are also present and acting destructively upon the tissues. This reducing effect, however, is less active at the positive than at the negative pole.

The peculiar value of this method is, however, that, in addition to the local destruction of tissue, the needle is rapidly oxidized and decomposed, and there is deposited an oxychloride of copper or zinc, which is carried by the cataphoretic property of the current and diffused, coagulating the blood in the vessels. The needle is roughened after a short contact, just as a nail is rusted, and sticks closely to the puncture, but comes away easily enough after reversal of the poles of

the battery for a few seconds. In the great majority of cases of angiomaticous nævi it is safe to make definite promise of a good result. The pigmented moles are best treated by negative electrolysis, and as the pigment is not deposited very deeply beneath the surface, the needle need not be introduced so deeply, better results being obtained by passing it just beneath the surface from one side of the mole to the other, repeating the process according to the size of the mark.

In all these cases there will follow for several hours some signs of cutaneous inflammation, which can best be treated by means of hot water. No great change in the appearance of the growth need be looked for at the time, but in the course of a few days a crust will form and come away, leaving in its place a slight scar, which constantly tends to become thinner and fainter. When the pigmented moles have hairs in them, a fine needle attached to the negative pole and introduced into the hair-follicle will cause the hair to come out with very slight traction. This is generally much more painful, for, while the moles themselves are not at all sensitive, the hair-follicles are, and a correspondingly weak current must be used.

#### A NEW TREATMENT OF CHOLERA.

It is stated in *La Médecine Moderne* of September 5, 1896, that CHAUVIN, of Liege, has employed with advantage the following treatment of cholera, particularly for the relief of the cramps and vomiting:

- ℞ Dilute hydrochloric acid, 15 minims;
- Pure pepsin essence, 20 minims;
- Wine of opium, 20 minims;
- Peppermint-water, 4 ounces;
- Syrup of orange flower, 1 ounce.

A teaspoonful each hour.

This dose can, however, be diminished as soon as the medicine controls the attack to some extent, so that four teaspoonfuls a day may be sufficient. Sometimes fifteen minims of ether may be added to this mixture with advantage. It is needless to say that the dose varies with the age of the patient. The advantage of this mixture is that the hydrochloric acid and pepsin produce an artificial but normal gastric juice which has a useful antiseptic and other influence upon the abnormal alimentary canal. It also facilitates the use of the opium, calms digestion, controls peristaltic movement, and diminishes the exudation of liquid into the intestine and the multiplication of micro-organisms.

#### THE USE OF GALLIC ACID IN THE TREATMENT OF TUBERCULAR HEMOPTYSIS.

In the *Journal des Praticiens* of September 12, 1896, DEGUY, after quoting the paper of Capitan, already published in the THERAPEUTIC GAZETTE, asserts his belief in the use of full doses of gallic acid in this condition. The doses he employs vary from four to fifteen grains, and may be given in powder, pills, or solution. A very useful mixture is ten grains of gallic acid in four ounces of infusion of orange; this quantity may be taken each day. In other instances, if the hemoptysis is very abundant, gallic acid may be advantageously associated with ergotin as follows:

- ℞ Gallic acid, 30 grains;
- Ergotin, 15 grains.

Make into twenty pills. Take five or more each day.

In other instances a prescription made up as follows is of advantage:

- ℞ Gallic acid, 2 grains;
- Ergotin,
- Powdered ipecac, of each, 1 grain;
- Powdered digitalis,  $\frac{1}{4}$  grain.

To be made into one pill.

Five or six of these pills may be used each day if necessary. In still other instances if cough is excessive the following may be used:

- ℞ Gallic acid, 2 grains;
- Sulphate of quinine,
- Ergotin, of each, 1 grain;
- Extract of opium,  $\frac{1}{4}$  grain.

Make into one pill.

Five such pills can be given each day.

#### THE USE OF TELLURATE OF SODIUM IN THE TREATMENT OF NIGHT SWEATS.

JOGET recommends in a thesis, which is quoted in *La Médecine Moderne*, August 26, 1896, the use of the tellurate of sodium in the treatment of the night sweats of phthisis; his observations having been made in the service of Barre.

Some of the readers of THE GAZETTE may remember that this drug was recommended seven or eight years ago, about the time camphoric acid was recommended for the same purpose. The effect which it produces, in the belief of Joget, is distinctly antisudorific. The initial dose is one-third of a grain a day in ordinary cases. If the tuberculosis is much advanced and the sweats are severe and general, it is necessary to increase the dose to one grain, but larger doses than this are apt to produce digestive trouble. For

persistent effect it is necessary to administer the drug for three consecutive days. Pills are the best form, but alcoholic or aqueous solutions are readily made. Thus a prescription may be written for:

Tellurate of sodium, 2 to 3 grains;  
90-per-cent. alcohol, 2 ounces.

A small teaspoonful night and morning in a little sugar and water.

It is claimed that this treatment will prove successful in sixteen out of twenty cases of tubercular night sweats. Its persistent use gives an odor of garlic to the breath.

#### THE SERUM TREATMENT OF SYPHILIS.

In the *Fortschritte der Medicin* of September 1 there is an abstract, by Dr. Dreyse of Leipsic, of an article of Tommasoli's, chiefly polemical, published in the *Giornale Italiano delle Malattie Veneree e Della Pelle*, called forth by the recent publications of Maragliano, Neumann, Mauriac, and Pellizzari, on the subject of the serum treatment of syphilis. He accounts for the fact that the treatment has accomplished less in syphilis than in other diseases, by the general lack of knowledge concerning the syphilitic virus, and the fact that all the lower animals are proof against the disease. As to the nature of the immunity of animals to syphilis, he believes this is due to materials that circulate in the blood, and is therefore hematogenous, while Pellizzari is of the opinion that the cause is closely connected with the tissues, since any congenital immunity must be of that sort, whereas acquired immunity must be set down as hematogenous. Tommasoli contends that, in the case of man at least, immunity, although acquired, may owe its cause to the tissues.

According to Pellizzari, the *conditio sine qua non* of immunizing experiments is that some material should be inoculated which, although but slightly virulent, is capable of exciting the production of immunizing substances in the tissues. "Is then," Tommasoli asks, "this condition fulfilled in Pellizzari's experiments, since he uses blood from human subjects whose syphilis is of eight, eleven, and thirteen years' duration?" A further objection made by Tommasoli against Pellizzari's experiments is that the most various kinds of serum were used on the same patients. He concedes, however, that possibly an amelioration of the course of the disease was the result.

Tommasoli next takes Mauriac to task for inaccuracies in his historical account of the

serum treatment of syphilis, and claims priority for himself; if he was not the first to give serum injections in syphilis, he says, he was certainly the first to reduce the treatment to a practicable method. He then combats Maragliano's contention that the immunizing agent in the lower animals is some substance peculiar to themselves, one of which little can be expected when it is transferred to man; also Pellizzari's doctrine that there is no hope of finding specific antitoxins in the blood of persons affected with tertiary syphilis. It may be, he says, that what we now call syphilis is really twofold—that we must distinguish between the contagious disease and the non-contagious diathesis, between syphilis and "syphilism" (sifilismo).

His most recent experiments are divided into three series. In the first method, which he calls hydrotherapy, he used the ascitic fluid of a person affected with syphilitic disease of the liver. This he employed upon seven patients in the secondary stage, most of whom had had no previous specific treatment. The smallest number of injections given in any one case was eight, and the largest thirty-seven, in periods ranging from ten to fifty-seven days, and the total amount injected varied from 68 to 350 cubic centimeters. The largest single dose was eighteen cubic centimeters. The fluid was obtained with all antiseptic precautions, and used either fresh or after being kept in sterilized vessels with the addition of a few drops of chloroform; it was injected into the buttocks, and no serious mishaps occurred in any case. In most of the patients, soon after the injection, there followed indisposition, headache, giddiness, etc., but these disturbances always subsided speedily; in some there was a slight elevation of temperature; in several the temperature rose and the weight increased during the treatment. No albumen was ever found in the urine. As to the effect on the disease, all that can be said with certainty is that new symptoms made their appearance during the course of injections.

In the second method, or galactotherapy, he used the milk of two women who had secondary syphilis, latent in one of them. After proper cleansing of the nipples, the milk was pressed out and injected immediately into the muscles of the buttock. Of seven patients treated by this method, one had gummatous syphilis, but all the others were in the secondary stage. The number of injections varied from three to thirteen, and the total

amount injected into any one patient ranged from 30 to 100 cubic centimeters. Ten of the patients in the secondary stage were decidedly improved; the others showed no change. This method was based on the observation that in other infectious diseases, such as tetanus and diphtheria, the antitoxins pass into the milk.

In the third method, termed myelotherapy, he employed large quantities of the spinal cord of the ox. He had previously seen syphilitics relieved of malaise and osteocopic pains, by eating freely of ox-marrow, without specific treatment. In all, nine patients were treated in this way. Six of them had severe headache and pains in the bones and joints; two of the six had before been treated with the ascitic fluid; four others had had no treatment. The three remaining patients showed fresh lesions of the skin and mucous membranes. The fresh spinal cord of the ox was given either in the form of balls having powdered liquorice incorporated in them, or in that of an emulsion with milk. The smallest amount given in twenty-four hours was 300 grains; the largest 1500 grains. Of the three patients with cutaneous manifestations, none showed any improvement, although the treatment was continued for fifteen, twenty-seven, and thirty days, respectively. Of the six others, only three were kept under observation for any considerable length of time; at the end of ten days they were all relieved of severe sufferings and felt perfectly well.

The third method, then, so far as these observations go, seems the most promising, but the propriety of classing it as a form of serum treatment may be questioned.—*New York Medical Journal*, Sept. 26, 1896.

#### THE SUBLIMATION OF CALOMEL IN THE TREATMENT OF MUCOUS PATCHES.

*La Médecine Moderne* of August 29, 1896, describes the results obtained by BALZER and by MARMONNIER. Calomel is sublimed by means of any one of the ordinary calomel sublimators used in medicine, and is then collected by means of an inverted funnel, and carried to the mouth of the patient through a rubber tube of small size. Half a grain to one grain of calomel is sublimated, and the vapor is allowed to pass into the mouth for a very short period of time. It is best to direct the vapor from the tube upon each individual patch for three or four seconds, and if the patient holds his breath for

that time comparatively little of the drug passes into his lungs. In the treatment of mucous patches about the genitals or the anus a similar method of direct application of the sublimed calomel may be resorted to. It is believed that this method of treatment is more efficacious than the application of nitrate of silver; the mercury is brought in direct contact with the syphilitic tissue, and it is not painful, as are nitrate-of-silver applications.

#### THE VALUE OF HOT SALINE IRRIGATION OF THE INTESTINE IN CASE OF UREMIA.

In the *American Medico-Surgical Bulletin* of September 26, 1896, GRANDIN states that he has seen cases where, after delivery of the fetus or after an abdominal operation, the kidneys refused to functionate, and where, with absolute certainty, uremic symptoms would supervene unless the excretory organs could be persuaded to do their duty anew. Acute suppression of urine to a greater or less degree, headache, spots before the eyes, clouding of the intellect, twitching—symptoms always of such bad omen—such is the clinical picture he has in mind, and for which he recommends, above the administration of drugs, continuous irrigation of the bowel with hot normal saline solution. While the catharsis which is indicated is awaited, while the problematical effect of one or another drug is hoped for, the intestine may be irrigated, with the result of most profuse diaphoresis and, in the relief of the congestion of the kidneys, the betterment of all the alarming symptoms. In the cases under consideration, what we aim to secure is free catharsis and diaphoresis, with consequent abstraction from the circulation of the toxic elements which are at the bottom of the alarming symptomatology. The physician is dealing with a complication which must either be relieved speedily or, as a rule, eclampsia, coma, and death ensue.

To irrigate the bowel properly he proceeds as follows: The woman is placed in the left lateral position, with buttocks elevated and head lowered. A large rectal tube is inserted into the bowel as far as may be, usually up to the sigmoid flexure. The rectal tube is connected with a gravity syringe, which is hung at least six feet above the patient's head. In case such a syringe be not at hand, the physician will find a funnel in every household, and this may be connected with the rectal tube by means of rubber tubing.

Hot salt water is used for irrigation. The strength of the solution should be about one per cent., and the temperature of the water in the receiver about 188° F. An attendant should hold the rectal tube at the anal margin to prevent its being expelled as, under the provoked peristalsis, the water is driven out of the bowel. From eight to ten gallons of water should be allowed to flow in. This accomplished, the woman should be wrapped in blankets and made comfortable in her bed. Meantime croton oil may be placed on the tongue, and glonoin may be administered in full doses hypodermically in the event of the character of the pulse demanding it. It may be stated here that, as a rule, in the condition under consideration, glonoin is called for, but the dosage must be large—that is to say, fully one-twenty-fifth of a grain, repeated half-hourly until the physiological effect has been secured. This drug offers us the readiest of all means for relaxing the spasm of the renal capillaries.

Very soon after the irrigation, profuse diaphoresis sets in, followed by abatement in the alarming symptoms, and shortly thereafter the kidneys may begin to excrete again.

The explanation of the effect of hot saline rectal irrigation is not far to seek. The nerve-centres are stimulated; the kidneys are directly stimulated; the skin is called into action; peristalsis of the intestinal tract is evoked. In short, every indication is promptly met.

#### THE TREATMENT OF HEMOPTYSIS.

In *La Médecine Moderne* of August 26, 1896, CAPITAN concludes an article upon this interesting subject. He divides the remedies which have been employed in the treatment of pulmonary hemorrhage into several classes, as follows: first, vaso-motor medicaments, or regulators of the circulation; second, those which act directly on the centres or nervous ganglia, as ergotin, hydrastis, hamamelis, digitalis, morphine, and atropine; third, those which act reflexly upon the nervous centres, emetics such as ipecac, tartar emetic, and full doses of Dover's powder, revulsives, purgatives, ice, hot water, and compression by ligature of the extremities. The drugs which act locally on the walls and on the contents of the blood-vessels are ergotin and the vegetable astringents, such as tannin, gallic acid, turpentine, or the mineral astringents such as alum, acetate of lead, iron, antipyrin, and sea salt. The general medicaments which can be

employed are the tonic stimulants such as alcohol, ether subcutaneously, camphor, sparteine, and quinine, and the sedatives, opium, morphine, and the bromides.

Capitan believes that ergot is an extremely useful remedy under these circumstances, but he also recognizes that there are certain contraindications to its use, as increased arterial excitement or hemorrhage from the venous trunks. On the other hand, in hemorrhage from an arterial blood-vessel which contains a large number of muscular fibres, ergotin is very useful, but in hemorrhage from the pulmonary blood-vessels its employment must be accompanied by caution because it augments the venous tension. Very much larger doses of ergotin than are used for ordinary purposes should be employed in such cases—five or ten grains—but care must be exercised not to give large enough doses to disorder the stomach.

The evidence concerning the value of hydrastis is somewhat contradictory: it is stated that in small doses it acts as a vaso-motor constrictor and augments the blood-pressure; it has, however, been employed with marked success by Huchard in tubercular hamatemesis. He gives twenty drops at a dose, repeated in the course of the day until the patient receives eighty drops. Should hydrastin be used, it may be given hypodermically in the dose of thirty minims of a ten-per-cent. solution.

He does not regard hamamelis as of great value in hemoptysis, but if it is used the fluid extract may be given in the dose of from fifty to eighty drops a day. Digitalis is necessary where there is in association with the hemoptysis marked evidence of cardiac failure; ordinarily, however, it is best not to employ it. Morphine is valuable because it quiets the heart and allays activity of the cerebral centres, so reducing blood-pressure; it is a very useful drug to associate with ergotin, and may be given in the dose of one-eighth to one-fourth of a grain hypodermically. Similarly, Capitan thinks, as did Brown-Séquard, it is often useful to combine with the ergotin and opium some atropine. In those cases where there is marked excitation of the arterial system, full doses of ipecac, sufficient to produce slight nausea, or tartar emetic, do good by reducing blood-pressure. In the way of revulsives and derivatives, active rubbing, or vesication, or the application of hot cloths or hot-water bags to the perineum, or ice in a small ice-bag to the chest, may be employed. If the hemorrhage

is sufficiently profuse to produce fainting, tight bandaging of the extremities is advisable. It is also claimed by some persons that where there is a slow persistent hemorrhage from the lung the use of an active purgative is useful, in that it draws the blood away from the affected part. Above all, it is necessary that the patient should be kept quiet. Whether much good is obtained from the administration of such vegetable astringents as tannin and gallic acid, is doubtful. Turpentine, however, in the dose of five to ten drops, sometimes seems of value.

Capitan believes that antipyrin is an exceedingly valuable remedy in hematemesis. Alcohol and ether, camphor and sparteine, along with quinine, are the drugs which are to be employed to overcome the intense weakness of the patient. Sometimes counter-irritation in the form of a sinapism or mustard plaster applied over the area in which the hemorrhage is supposed to originate is of advantage. The following prescription may be used for hypodermic injection:

- ℞ Ergotin, 75 grains;  
Hydrochlorate of morphine, 1 grain;  
Antipyrin, 20 grains;  
Sulphate of sparteine, 3 grains;  
Sulphate of atropine, 1-30 grain;  
Distilled water, enough to make 3 drachms.

Of this, twenty minims may be given hypodermically, deeply injected into one of the muscles of the back or chest, and if necessary the injection may be repeated in half an hour should the danger be pressing. It is also advisable to administer part of the following prescription by the mouth every half-hour with a teaspoonful of broth:

- ℞ Ergotin, 30 grains;  
Gallic acid, 7 grains;  
Turpentine, 5 minims;  
Syrup, 4 ounces.
- Dose, a dessertspoonful to a tablespoonful.

#### CHLORATE-OF-POTASSIUM POISONING.

ISAACS contributes to the *American Medico-Surgical Bulletin* of August 22, 1896, a well prepared and largely bibliographical article on this topic. He tells us that the first symptoms of poisoning are thirst, and discomfort about the stomach, followed by pains in the epigastric and hypogastric regions and the loins. The heart action is at first increased, with full and bounding pulse, soon to be followed by weak heart-beat, with pulse small and thready or almost imperceptible. Vomiting, generally very severe and persistent, is among the first symptoms and almost invari-

ably present, but may be absent when small portions of the dose are taken at intervals and slowly enough to allow of absorption as fast as taken. Diarrhea is a constant symptom, one of the first to appear and last to disappear. The stools are fluid and black or dark-green, or, as in the writer's case, black flocculi in a bright yellow fluid. Tenesmus frequently accompanies the diarrhea.

On the kidneys the first effect is an increased secretion of urine, with irritation of the bladder, which, if the dose has been large enough, is soon followed by dysuria and suppression, which may become complete. The little urine passed is almost black, deposits a sediment containing granular and hyaline casts and blood-corpuscles, and generally also contains a large amount of albumen. There may be, even in a fatal case, no noticeable suppression or discoloration of the urine, as in the cases of Drs. Sherer and Boude, both of which were fatal, and in the writer's own case, in which all the other symptoms were as severe as they could be and yet recovery follow. In the first two no examination for albumen is noted, but in the writer's there was no albumen in the urine. As to chlorate of potassium in the urine, Isambert's experiments go to prove that it is largely eliminated in this way, that it appears in fifteen minutes after ingestion of the drug, and continues for from fifteen to forty-eight hours. In none of the cases cited is any test for this mentioned, but in the author's own case, although the potassium was sought for, none was found—the quantity of urine obtained, however, was too small for proper examination.

Cyanosis is an almost constant symptom, and may be of the whole surface or of the extremities, and especially of the ears, nose, lips, fingers, and toes. It is usually accompanied by dyspnea, more or less by coldness of the extremities, and sometimes by rigors. In cases where this condition is marked, the hue of the surface is not always that of ordinary cyanosis, and is variously described as "blue as indigo," "bluish-ashen," "bluish-white-dusky," "resembling anemic skin discolored with nitrate of silver," and in the author's own case it was so decidedly dusky as to approach chocolate-color. He accounts for this by the simultaneous existence of jaundice, which at the time was to be recognized on the white of the eyes only, but with the subsidence of the cyanosis it became evident over the whole surface. The marked anemia caused by the destructive action of the

poison on the blood also contributes to modify the appearance of the cyanosis. Jaundice is often present, and, as above noted, when cyanosis is marked, it is visible only on the conjunctiva.

On the blood the salt evidently has a very destructive action, but what this action is does not seem to be understood. Different writers claim disintegration of the red blood-corpuscles, reduction of hemoglobin to methemoglobin, and change in the color of the blood to a chocolate hue. Of the cases cited in this article, in three, all of which resulted fatally, the results of microscopic examination of the blood are given: in only one was any change in the corpuscles noted, showing "altered blood-disks in masses as well as unaltered blood-corpuscles;" the other two showed no change in the red blood-cells, but in one there was an increase in the proportion of leucocytes. One of the cases (Dr. Willie's) showed chocolate color of the blood, but it is not stated whether this was ascertained from the blood itself or from the color of the surface, which might have been similar to that in the writer's case.

On the nervous system the effect of the poison varies from the production of headache and prostration to stupor, coma, or convulsions. Stupor followed by coma, either partial or complete, is generally present in severe cases. Remission with apparent improvement may take place, only to be followed by relapse of all the symptoms. Depression may alternate with mental excitement. Paralysis of the muscles of vocalization and deglutition was noted in one case, which eventually recovered.

#### AN OPERATION FOR VALVULAR STRICTURE OF THE URETER.

FENGER (*American Journal of Medical Sciences*, December, 1896) reports a case of valvular stricture of the ureter operated upon successfully. In cases of hydronephrosis or pyelitis with distention (pyonephrosis) it is not uncommon to find comparatively narrow or thin-walled semilunar valves located transversely in the ureter. These open upward, have the same mechanical action as the valves in veins, and stop the passage of liquid through the ureter on its way from the kidney to the bladder. They are sometimes single and sometimes multiple, two or three in the same ureter. They have been depicted in Rayer's atlas, and are not uncommonly mentioned in the descriptions of specimens in the litera-

ture. They cause a gradually increasing impediment to the flow of urine, and effect dilatation of the ureter above and usually near to the valve, so that a ureter with multiple valves will present as many dilatations and constrictions as there are valves. It is natural that if small stones form in the kidney they should be arrested at the valves.

The patient, Mrs. G., aged thirty-two, in 1880, at the age of seventeen years, after jumping from a wagon to the ground, at once experienced pain in the right side immediately under the ribs, so severe that she fainted; probably the kidney was dislocated. Remittent attacks of pain followed, reawakened after her first pregnancy, in 1885, to disappear for eight years, returning in 1893, subsequent to miscarriage, to become intermittent or almost constant. Pyonephrosis, with tumor of right kidney, was diagnosed. Pelviotomy was performed August 6, 1895, as follows:

The patient was anesthetized with ether and placed on the left side on a cushion. An incision was made between the twelfth rib and the rim of the pelvis forward for about nine inches from the border of the erector spinæ muscle. The kidney was large, with but little perirenal fat, and was freely movable. Two small cysts presented on its convex surface about the size of a pea, which contained clear fluid. A part of the kidney-tissue which included these cysts was removed for examination. After isolation of the pelvis, which was somewhat dilated, but in which no stones could be felt, Fenger laid bare the ureter and felt a nodular mass two inches below the pelvis. He then incised the pelvis longitudinally, and about an ounce of urine escaped, from which cultures were subsequently made. The little finger was then inserted into the dilated ureter for an inch without discovering a stone, but upon manipulation with the other hand four stones were squeezed up into the pelvis and removed. A sound passed down from the pelvis into the ureter was arrested two and half inches below the pelvis, at a point where a somewhat soft thickening was felt on palpation. A longitudinal incision was now made, three-eighths of an inch long, into the ureter, upon the end of the sound above, through and below a transverse valvular stricture. A probe inserted through the opening in the ureter below the stricture passed easily down into the bladder. By holding the longitudinal wound open and stretching this part of the ureter over the index finger the operator was enabled to clip off the valvular stricture

from within the ureter with scissors, leaving the muscular and internal coats of the ureter intact. A plastic operation was performed on the ureter, and a No. 12 flexible bougie inserted from the wound in the pelvis into the ureter. The wound in the pelvis was left open. Upon digital exploration through this wound, the calices were found moderately dilated, one of them containing a small stone, which was removed. No other stones were found after careful examination. On this account it was not considered necessary to incise the kidney on its convex surface. Rubber drainage-tubes were then inserted, one down to the wound in the ureter, and another to the pelvis of the kidney; these tubes were surrounded with gauze. The external wound was closed with heavy silk sutures.

The operation lasted two hours. At the close the patient was in good condition, pulse strong, respiration good. She vomited twice after the operation. In the evening she was catheterized and two ounces of dark-brown urine withdrawn. She complained of severe pain in the wound. During the night she passed four ounces of urine, but toward morning the pain decreased, and she finally recovered entirely.

It will be seen that the operation for infected cysto-nephrosis in this case was not nephrotomy, as the convex surface of the kidney was not divided at all. Pelviotomy was performed, partly for the removal of the stones squeezed up out of the ureter, and partly for the exploration of the ureter and calices.

Exploration of the ureter with the sound led to the detection of the stricture, a valve, which was excised through a longitudinal opening in the ureter at its seat. Fenger considers this operation preferable to excision of the entire wall of the ureter and invagination after Van Hook's method, as it gives the least possible shortening of the canal. This may be of importance if more valvular strictures have to be operated upon.

Exploration of the calices can be made through an incision in a somewhat dilated pelvis when the latter is wide enough to permit of exploration with the finger and sound. For additional security against leaving stones in hidden calices with narrow entrances, it would be well to explore through the convex surface of the kidney with steel needles. When this is done in addition to digital exploration through the pelviotomy wound, there is as little risk of overlooking stones as if the convex surface of the kidney were

divided; moreover, hemorrhage is avoided, the operation on the renal pelvis being entirely bloodless.

For the local treatment of pyelitis, drainage through the wound in the pelvis will be sufficient, at least in ordinary cases of stones and valves in which, by removal of the cause, we may reasonably expect the pyelitis to come to an end.

#### *TREATMENT OF BACKWARD DISPLACEMENTS OF THE UTERUS.*

H. A. KELLY (*American Journal of the Medical Sciences*, December, 1896), in a paper on the above subject, reaches the following conclusions:

The various operative methods cited for treating retroflexions resolve themselves into two classes: the direct, which attack the body of the uterus; and the indirect, which deal with the uterus mediately by the round, the broad, or the utero-sacral ligaments. Of the indirect methods, the two which promise the best results are: that of Pryor, acting through the vagina on the cervical end of the uterus in order to produce enough scar-tissue about the utero-sacral ligaments to hold the cervix well back in the pelvis; and that of Pagenstecher, which endeavors to accomplish the same thing by suturing and shortening the round ligaments. The other indirect method is that of Alexander, acting upon the opposite pole of the uterus by means of the round ligaments; the best elaborated technique of this procedure is that of Dr. Edebohls, of New York.

The direct methods are two: vaginal fixation, and abdominal fixation or suspension. The vaginal operation has been practically abandoned, and the only abdominal operation which has thus far stood the test of prolonged trial in a number of cases is Kelly's. His method is as follows:

The case is carefully selected, avoiding patients who are simply hysterical and whose complaints are of a general nature in no way dependent upon the local lesion; also those whose symptoms are not pronounced, but who apply for treatment simply because they imagine they cannot have good health as long as retroflexion exists.

If the case is one calling for operation in a woman who has borne children, the vaginal outlet should first of all be seen to, and restored if it is broken down.

The operation of uterine replacement is performed in the following manner:

The instruments needed are a needle-holder, curved needles, scalpel, silk suture, two pairs of artery-forceps, silver wire and catgut, and an elevator.

After due preparation of the patient, the bowels and bladder having been freely evacuated, she is placed upon the operating-table with hips elevated. It is best to leave her in this position one or two minutes before opening the abdomen, in order to allow the intestines to gravitate toward the diaphragm. An incision three to four centimeters long is then made just above the symphysis pubis in cases in which the abdominal walls are thin or of medium thickness; a longer incision may be necessary in stout women. The length of the incision is less than in any other abdominal operation except for evacuation of ascitic fluid, and owing to its low position the scar is in time completely hidden, in the course of a year or two becoming scarcely visible.

The peritoneum is opened the full length of the skin incision, caught at once on both sides with forceps, and drawn outward. One or two fingers are now introduced through the incision, and the fundus of the uterus caught and raised into ante flexion.

Kelly invariably uses, as suture material for suspending the uterus, a medium-sized silk, about a half-millimeter in diameter; catgut is absorbed too quickly to insure permanent adhesion, and he has had no experience with silkworm-gut or silver wire, silk being so much easier to handle and having given such perfect satisfaction.

The suture is passed in the following manner: One side of the incision is lifted up by two fingers so as to expose a portion of the anterior abdominal wall on its peritoneal surface. The movable peritoneum and sub-peritoneal tissues are then transfixed with a curved needle at a point one or two centimeters away from the lower angle of the incision; the amount of tissue taken is about one centimeter in width and two or three millimeters in depth. The same suture is then passed through the posterior face of the uterus, one or two centimeters back of the fundus, and finally brought out through the peritoneum and sub-peritoneal tissue on the opposite side of the abdominal wall at a point corresponding to that of entrance. When this suture is tied, it at once brings the uterus up snugly against the anterior abdominal wall in ante flexion.

One more suspensory suture, is all that is needed to hold the uterus permanently in

ante position. This is passed like the first, but about a centimeter higher up on the abdominal wall and a half-centimeter lower on the posterior surface of the uterus.

The second suture having been tied, the abdominal wound is closed by sewing up the peritoneum with one or two silver wire mattress-sutures, and finally closing the superficial fat and skin with continuous catgut sutures. Before the peritoneum is completely closed the patient should be dropped to a horizontal position to let the air out from the peritoneal cavity.

Sometimes, when the uterus is brought forward out of retro flexion, the fundus lies so deep in the pelvis, and is so completely covered by coils of intestine, that it is exceedingly difficult to get at it to pass the first suture; in the average case the symphysis pubis forms a satisfactory point of counter-pressure to support the fundus pressed against it by two fingers while the first suture is being passed; but in the class of cases referred to, when this simple maneuver does not avail, the fundus may still be brought within easy reach by using an elevator, forming an artificial point of counter-pressure during the introduction of the suture.

Upon closing the incision a simple dressing of dry sterilized gauze is applied, and the patient is kept in bed for three weeks. After getting up she ought to take only gentle exercise for some weeks longer, and for at least six months avoid lifting and heavy work. The bowels should be kept emptied at regular intervals, and, above all, the bladder should be emptied not less than once in three or four hours, according to the amount of excretion; it is possible for an overdistended bladder to tear a suspended uterus away from its moorings.

Between October 1889 and October 1896, Kelly has operated upon two hundred cases of retro-displacements in the Johns Hopkins Hospital and upon nineteen in his private hospital, besides other cases operated upon outside. In no case has there been a death in any way connected with the operation, either during the convalescence or at a remoter period, and he knows of no case in which there has been a hernia or any serious interference with any function of the bladder. In tracing the subsequent histories he has learned of pregnancy in fourteen cases, in but one of which was there any difficulty attributed to the operation; that was one of the earliest cases, operated upon in 1889, in which a protracted suppuration in the wound

brought about such dense adhesions between the fundus and the abdominal wall that the patient, at the termination of her labor some years later, was only delivered by the forceps. Kelly has seen but four failures after this operation.

The operation just described relieves the retroflexion by holding the uterus in a position of great mechanical advantage to meet the forces which tend to displace it. The intra-abdominal pressure now falls upon its posterior surface and, instead of tending to produce a retroflexion, actually increases the antelexion. While the immediate effect of the operation is to fix the uterus to the anterior abdominal wall (ventro-fixation, hysteropexy), this is not the final result obtained, which is a suspension of the uterus by its posterior surface, allowing it the full freedom of all its normal movements. If, for example, the patient is examined two or three months after the operation, the body of the uterus will be found lying in easy antelexion in contact with the anterior abdominal wall; the examiner will also find that he is able to raise it without resistance, and to push it backward or sidewise. One position, however, it will not take; he cannot throw it again into retroflexion. The explanation of this freedom of motion is found in the connection of the uterus with the anterior abdominal wall by one or two bands of adhesion.

Almost all writers upon the subject of the operative treatment of retroflexions have been in the habit of discriminating between various classes of cases; for example, a distinction is made between those past the childbearing period and those still within it; and operations such as vagino-fixation, which experience has shown ought not to be performed during the childbearing period on account of the danger to patient and child in case of pregnancy, may very properly be performed in a woman who is not likely to become pregnant.

A distinction generally recognized is that between adherent and mobile retroflexions. Some operators, while unwilling to open the peritoneum in the case of a non-adherent movable uterus, feel that sufficient justification for celiotomy exists when there are posterior adhesions or disease of one or both adnexa. Although this distinction was emphasized at the recent Gynecological Congress at Geneva, the author has not dwelt upon it here, as he has shown by his own statistics that the danger to life from a properly per-

formed suspensory operation is no greater than in any of the so-called simpler operations. In addition to this, the peritoneal incision affords an opportunity for inspecting the appendages and discovering diseases often unsuspected, such as hydrosalpinx and adhesions of less grade; in one of Kelly's cases a commencing papilloma of the right ovary, not larger than a split pea, was found.

---

#### THE CAUSES OF DEATH AFTER LAPAROTOMY.

FRITSCH (*Medical Press and Circular*, Oct. 28, 1896) calls attention to the fact that the body is not often free from germs, and that different tissues behave differently under invasion of bacteria; that, in general, various people have various affinities as regards various cocci. Cocci are rapidly swept into the peritoneum and into the blood, and destroyed. But in order that they may be harmless, there must not be too many of them; the heart of the host must be healthy and his circulation undisturbed—conditions that are opposed by prolonged operation under chloroform narcosis, loss of blood, and cooling; and the functions of the tissues must be normal. Cooling is of less moment than contact with air, and the altered pressure after opening the abdomen. The injury thus caused is often visible to the eye. It is still greater when the peritoneum is roughly and improperly treated. Even without direct infection the operation is dangerous. It must not be forgotten that cocci accidentally introduced or coming through from the intestines may find conditions suitable for their growth. Generally the weakened intestines recover their tone. If, therefore, after twenty-four hours the heart is strong and the pulse good, there is no danger; but if, with a weak heart and a quick pulse, the normal function of the bowel is not restored, there is. The two conditions which strongly predispose to infection are: injury to the heart, and interference with the peritoneum or intestinal functions. Patients on whom laparotomy has been performed do not die because they have become infected, but they become septic because they die or while they are dying.

The course of unfavorable cases is the following: After the operation patients wake distressed; breathing is heavy; the bandage presses heavily; the characteristic symptom is the cardiac weakness and the quick, feeble abdominal pulse that is almost pathognomonic; the abdomen becomes distended, the

countenance pale; there is thirst and vomiting, increase of temperature, and tympany; the pulse becomes worse. These symptoms are not due to ileus, peritonitis, or sepsis.

The logical deduction from this view is that in cases of organic or weak heart we should not operate, but wait. Before operation, starving or drastic purgation is contra-indicated. The technique must be good; the after-treatment, very careful washing out of the stomach, warm enemata, tonics, quinine subcutaneously. Lives are to be saved by careful selection of cases, good preparation, conservative operation, and careful after-treatment.

#### THE STERILIZATION OF SYRINGES BY BOILING.

In a communication to the *Centralblatt für Chirurgie*, 1896, No. 27, HOFMEISTER claims to have solved the question of the sterilization of syringes. Although much time and thought have been expended in the effort to devise means by which syringes for surgical and bacteriological purposes could be easily and quickly rendered sterile, no satisfactory method has been proposed heretofore. Of all the new patterns of syringes that have been recommended, none has sufficient merit to displace the old form with the leather packing, and yet it has not been possible to make the latter aseptic.

The observation, by the author, of the fact that catgut could be boiled without injury after first hardening in formalin solution, led him to apply the same process to leather. It was found that common leather which was allowed to stand for twenty-four hours in a two- to four-per-cent. solution of formalin could be boiled in water without losing its softness, durability, or elasticity. Leather so prepared has been boiled for ten hours without damaging it; a slight deepening of the color was the only change to be observed. On the contrary, leather not so treated becomes, soon after boiling, so soft as to be useless, and can be torn easily; after drying, it makes a mass as hard as stone, which can be crushed into powder.

The experiments brought out the fact that the formalin leather which was boiled one hour each day for several days, and dried each time, retained its natural and useful qualities better if subjected to the formalin solution before each boiling than if macerated once only.

These experiments led him to adopt the following process for sterilizing syringes:

1. Only such syringes as consist of glass, metal and leather are suitable. The metal parts should not be fastened by putty, but should be screwed to the cylinder.

2. The piston with the leather packing is taken out and placed in ether or benzin to remove the oil.

3. It is then transferred, for twenty-four to forty-eight hours, to a two- to four-per-cent. formalin solution.

4. After rinsing thoroughly, the syringe may be put together and is ready to be boiled.

5. When ready for boiling, the air is to be driven out of the cylinder by filling with water. Glass syringes should be put in cold water and gradually heated.

6. From time to time the piston with the leather packing is to be placed again in the formalin solution. After removing the oil the leather should be examined to see that it has not shrunk. If the piston fits closely, then it will not shrink in the subsequent steps of the process.

After two months' trial the method has proved itself to be practical.—*American Journal of the Medical Sciences*, November, 1896.

#### TREATMENT OF VENEREAL BUBOES.

PERRY (*American Journal of the Medical Sciences*, November, 1896) considers the treatment of non-suppurating buboes under the headings: (1) by external applications; (2) by the hypodermic injection of medicinal agents into the substance of the gland; (3) by incision; and (4) by excision.

The most important means to employ when a bubo is seen early and it is decided to try abortive measures, are rest in bed, belladonna ointment, and spica pressure of the groin. In a very few cases these measures will cause a disappearance of the inflammatory symptoms. The writer has long since given up this treatment, however, as unreliable and unsatisfactory, and now treats all buboes seen before suppuration by another method.

Several antiseptic substances, for injection into the inflamed gland, have been used as a means of aborting buboes. Dr. M. K. Taylor several years ago called the attention of the profession to this method of injecting a solution of carbolic acid; he claims that one injection generally succeeds in aborting a bubo, that suppuration is rare, and that a cure is effected in eight to ten days. He uses a solution of ten grains to the ounce, and injects twenty to forty minims.

Harvey also speaks of the efficacy of this treatment, and says the time of election for the injection is just prior to suppuration. Others have tried carbolic acid, but have been disappointed with the results obtained, and at the present time this agent is seldom employed.

A one-per-cent. solution of bichloride of mercury has also been highly lauded as an efficient remedy in this class of cases. Nannino reported twenty-seven buboes successfully treated by injecting this drug. The author has treated five cases by this method, in all of which there was intense pain, produced by the medication, that lasted for hours; in one case there was severe constitutional disturbance, the febrile symptoms lasting six days; and all went well on to the formation of an abscess, necessitating an incision. The average duration of treatment in these cases was seventeen days. He soon discontinued the method on account of the severe pain it produced.

Dr. Welander, who first called attention to the marked influence of benzoate of mercury in the treatment of buboes, reports some extraordinary results, and says that in the majority of non-suppurating cases it will cause a subsidence of the inflammatory symptoms in a few days, and that resolution will be prompt. Of seventy-eight cases reported by him, fifty-six were cured without any suppuration; but in the remaining number some pus formed in the centre of the gland, necessitating a puncture. Spitschka confirms the results of Welander. Brousse and Botherat reported ten cases treated by this method, nine of which suppurated.

The writer's experience with the benzoate of mercury has been so satisfactory that he employs it in the treatment of all non-suppurating buboes, and also in those in which the formation of pus is suspected but distinct fluctuation is absent. In fact, his experience teaches that it acts most beneficially in buboes in which suppuration is threatened.

The injection should be made under the same aseptic conditions as when a surgical operation is contemplated. He generally injects twenty or thirty minims with a hypodermic syringe, passing the needle well into the substance of the gland at one or more points.

The medication causes a burning pain, which usually lasts about two hours, and some constitutional disturbance; fever ranging from 99° to 104°, and continuing for a few days. In some cases there is rise in

temperature only after the first injection, while in others there is an elevation after each use of the drug. The shortest period of fever recorded was one day, the longest six days, and the average three days.

In two or three days after the commencement of treatment the bubo is much diminished in size, and resolution is taking place. In all of the author's cases some pus, generally small in amount, formed in the centre of the inflamed gland, but at the same time resolution was taking place in the periphery. As soon as any suppuration is detected, a small puncture is made, all the pus squeezed out, the small abscess-cavity irrigated with peroxide of hydrogen, and an antiseptic dressing applied. In a few days all discharge ceases, the remaining induration rapidly subsides, and the bubo is cured.

In all, Perry has treated twenty-two cases by injection with one-per-cent. solution of benzoate of mercury in non-suppurating buboes. In all, 306 days' treatment was given, and the average time necessary to effect a cure was 13.9 days.

He considers this treatment far superior, in the majority of buboes, to excision of the inflamed glands, since it is a trivial one, there is no danger of an accident and no need of an anesthetic, the scar is scarcely noticeable, and the time necessary to effect a cure is much shorter. 'On the other hand, the excision of a large bubo is not a simple operation; it leaves a large cavity which, in the vast majority of cases, must heal by granulation, weeks being consumed before cicatrization; and finally a large and unsightly scar is left. Again, discarding everything in this comparison except the element of time, and weighing the most favorable statistics the author has seen on excision—union by first intention in one-half of the cases—still the scales tip in favor of the benzoate treatment.

In recent years excision has become the favorite method of many surgeons for treating non-suppurating buboes, but the results obtained have been so unsatisfactory that several who formerly excised all inflamed glands have abandoned the operation and treat by external application until pus forms, when the bubo is incised and treated as an ordinary abscess.

Excision of all implicated glands means a difficult and somewhat hazardous operation in a dangerous anatomical region. Accidents have happened in the hands of the most skilful operators; the most serious are wounds of the femoral and internal saphenous veins.

nous veins. The hemorrhage is often profuse, and complete enucleation of all the diseased glands leaves a cavity that seldom heals before considerable time has elapsed.

Dr. Watson believes in thorough excision, and reports twenty unselected cases, in ten of which he secured union by first intention. His statistics are the most favorable, and probably few other surgeons have been as successful. Martin says the time consumed will be from two to eight weeks, depending upon the size of the bubo excised.

The treatment of suppurating buboes may be (1) by incision and treating as ordinary abscess; (2) by incision and curettement; (3) by puncture, evacuation of pus, and distention of the cavity with medicinal substances; and (4) by thorough excision of all diseased glands.

The treatment by incision alone has not yet yielded very brilliant results, the average number of days consumed being thirty-two.

Incision and curettement has not given much better results than simple incision. It is true, though, that the cases in which curettement is used are generally more severe, and consequently the results are not so favorable as if this extreme measure were used in all suppurating buboes. This treatment is advisable in those cases in which the skin has been destroyed and there is left an unhealthy granulating ulcer.

Karl Szadex reported 274 cases of suppurating buboes treated by incision, curetting, and packing with iodoform gauze. The average duration of treatment was thirty days.

Dr. Scott Helms removed the pus by aspiration, injected the cavity with a solution of carbolic acid, and after this was thoroughly squeezed out, distended the abscess cavity with a ten-per-cent. iodoform ointment.

Fontan treated the incised bubo with iodoform and vaselin, and reported forty-one cases. The average time of treatment was six or seven days.

Dr. Otis reported sixteen buboes treated by this method; nine were cured in six days, one in fourteen days, and one in twenty-three days.

Dr. Hayden describes his treatment as follows: Make a small puncture through the skin at the most fluctuating point of the bubo; thoroughly evacuate the pus; irrigate the cavity with peroxide of hydrogen, then with bichloride solution, 1 to 1000; press out all the fluid; distend the cavity with warm vaselin holding in suspension ten per cent. of

iodoform; and apply a cold bichloride dressing to favor congealment. The patient should be kept quiet for forty-eight hours, and the dressings removed on the third or fourth day; if no pus has formed, another injection of iodoform ointment is not necessary; but if the suppuration has not entirely ceased, the bubo should be re-dressed in the original manner. He reports fifteen cases, in which the average duration of treatment was twelve days, and in twelve of these one injection was sufficient.

From the above statistics the writer states that he is led to conclude:

1. That buboes are probably caused by the absorption of chemical poisons, the result of the action of the micro-organisms in the chancre, and not by the entrance of the micro-organisms themselves into the lymphatics.

2. That the benzoate of mercury yields such satisfactory results that it should be employed in the treatment of non-suppurating buboes, and excision reserved for those cases in which benzoate has failed.

3. The injection of iodoform ointment should be used in the treatment of all freely suppurating buboes, since statistics show that it yields much more satisfactory results than the other methods of treatment applicable to this variety.

4. Incision and curettement should be used in a few cases in which the skin has been destroyed and the ulcer presents an unhealthy granulating surface.

5. Excision should be reserved for cases that have not yielded to other treatment, and for those in which there are several foci of suppuration.

#### *DRAINAGE IN ABDOMINAL SURGERY.*

BISHOP (*Medical Press and Circular*, Oct. 28, 1896), after a consideration of the theoretical advantages of drainage, holds that artificial drainage is distinctly required in operations on tubes, wherever practicable, and in all septic operations; that it is beneficial in cases where pure asepticity is doubtful; and that it is distinctly hurtful in cases which are absolutely aseptic and in which the patency of a tube is not involved.

The means by which drainage may be carried out are very numerous, and must be adapted to the nature of the case. The central idea is a tube of some kind, and a force by means of which the tube is emptied and kept empty, so that the end nearest

the absorbent wounded surface is kept dry. The tube may be a large one, as in the glass tube used often after laparotomy, or an extremely minute one, as in the case of drainage by strands of silk or gut. The force may be supplied by a suction-pump, as is done in drainage by a large glass tube; or it may be capillarity, as in Mikulicz's gauze drain; or, again, the action of gravity—this is not often obtainable in abdominal surgery, although it is sometimes taken for granted when using a vaginal drain; and, lastly, the tube may be a natural one; and the force also one of the natural forces of the body, as in drainage by the intestinal canal, where the force is that exerted by the muscular wall of the intestine.

The materials used for drainage may be best considered when the matters drained have been reviewed. These last are blood, lymph, pus, bile, urine, and feces.

Blood simply should never require artificial drainage, being in itself aseptic. If it exists in quantity, it means a bleeding vessel, which requires pinching, torsion, ligature, sponge-pressure, cautery, or solid astringent, as the case may be. If the amount lost is less than this, and is aseptic, it will be absorbed and will do no harm; if more, it will clot and block up any drain introduced, and in an hour the drain will be perfectly useless. The true way of dealing with small quantities of blood or large amounts of lymph is by setting the natural suction-pump to work. This will be referred to later.

Lymph is a material which does not require drainage, for the same reason. It does not show its presence in quantity at the time of operation, and should be looked upon as building material pure and simple. If the amount thrown out is more than is required, it should be left to the natural process, which will soon dispose of it.

The presence of pus may be said to be the one main reason for drainage. Pus may escape into the general peritoneal cavity before an operation, as in pyosalpinx. In most of such cases it is advisable to leave a drain when closing the abdominal wound, so that any material of this kind left behind may be carefully removed. If the abscess can be opened without disturbing the limiting adhesions or membrane between it and the peritoneal cavity, drainage of the abscess itself is imperative, and this can often best be done by a gauze drain *a la* Mikulicz. By this means the space can be kept dry, the inner pledgets of gauze being frequently

changed, while the actual surface of the walls is not disturbed. More especially is this mode of drainage useful if the walls of a cavity have to be sewed to the parietal peritoneum in consequence of inability to finish removal of suppurating cyst from too intimate adhesions to the surrounding structures.

When the exit of bile has to be provided for, rubber tubes are probably the best to use; glass would be preferable, but the irritation of its inner extremity and the possibility of fracture is against its use in this situation.

When urine and urinary organs are in question, we require drainage in three situations, for different reasons.

In the region of the kidney, if the kidney has simply been opened, we require a drain to carry off as quickly as possible the unavoidable leakage of urine, and prevent its infiltration into the connective tissue and fat around; and here large-size rubber tubes are best. In this position, gravity is the force available. When the kidney has been removed, it is wisest to use a tube for two days, since air is sucked into the tissues by the respiratory movement of the diaphragm, and without a tube its exit is impeded by the valve-like action of the soft tissues which encompass the cavity produced. But the outer opening of the drainage tube must be very carefully protected so that any air that enters may be rendered aseptic by passing through cotton wool or gauze.

MacEwen introduced the use of decalcified chicken-bone drains. The writer has not had satisfactory results from their use. The idea is to obtain a drain which shall not require removal—that shall act during the time required, and then become absorbed, so allowing the original dressing to remain unchanged until healing is complete. The chicken-bones do act for a while, but then they form a flocculent mass which effectually blocks the further exit of fluid and delays effective union. The same objection applies to catgut strands, which make a smaller but hardly less objectionable mass.

Drainage by capillarity is the object sought to be obtained by the latter method, as also by strands of horse-hair or silkworm-gut. Horse-hair is inadmissible inasmuch as, owing to the manner in which the epidermic scales of which it is composed are set, it will travel either into or out of the wound in which it is placed. Silkworm-gut is the best material for this kind of work. But drainage by capil-

larity appears to be based entirely on a false idea; only serum, blood and lymph can be removed by it, and these imperfectly, and if the wound be aseptic the method is ineffective.

The most important means of drainage we possess in abdominal surgery, however, is the natural suction-pump, the intestine. This is an advantage which abdominal surgery possesses over that of all other regions in the body. All writers on the after-treatment of laparotomies, etc., lay stress upon the desirability of securing early action of the bowels, and such action is looked upon as in most cases securing safety from peritonitis. But the exact manner in which that safety is produced has not, as far as the writer knows, been clearly defined. It is not, of course, merely because the lower bowel has been emptied, that an operator feels safe. The presence of decomposing, offensive material in the rectum is, of course, objectionable, but the absorptive power of the rectal mucous membrane is not great, and the mere removal of this load would not make the immense difference to the prospects of the patient that is associated in the surgeon's mind with the fact that the bowels are in action. Moreover, in all these cases the bowels have been cleared before operation, and often enough the amount passed is but small in comparison with the relief experienced. Indeed, the surgeon is not very anxious about any patient who has passed flatus naturally, even if no solid matters have escaped per anum. The passage of a stool only emphasizes the fact that the bowel is acting normally, and shows that it does so with a fair amount of strength.

The small intestine fulfils many duties in the economy, but for our purpose, and after operations involving the peritoneal cavity, it may truly be looked upon as a living suction-pump, or a long sponge, which when properly acting, by the vermicular action of its muscular coat, is constantly drawing up, through the myriad stomata in its serous coat, into the lymph-channels of its walls, all fluids from the cavity which it completely fills, and forcing such fluids onward into the bloodstream, where they can be dealt with by the various excretory organs. By its steadily recurring rhythm of contraction and relaxation not only are its fecal contents passed on into the rectum and so out, but any fluids in the peritoneal cavity are sucked up and pressed onwards away from the free surface of the peritoneum, where they might form a

stagnant pool in which bacteria could develop. Thus the salutary result of the action of the gut is not due to the actual passage of feces through it, though doubtless this assists, but to a separate function, the activity of which, however, we can gauge by the coarser and more visible results.

That the utmost good may result from such action, it is evident that it should be started soon. Should it be delayed, the amount of fluid to be disposed of in the abdominal cavity may become too great to be easily and expeditiously carried away; some fluid will then remain in a state of rest, under conditions of warmth, etc., eminently favorable to the development of bacteria; and when this in its turn is absorbed, poisoned toxins are present and are absorbed with it, producing septicemia, or the paralyzing effect of these toxins may be so great as to prevent any effective action on the part of the natural suction-pump. Peritonitis will then rapidly develop.

Tait, as is well known, advises the use of saline aperients, seidlitz powders to be begun at the earliest possible moment upon the appearance of any sign of peritonitis. If the foregoing explanation of the benefit to be derived is correct, however, it will be seen that it is wiser not to wait for any such signs, which evidence the result rather than the cause of the necessity for such action. The natural suction-pump will act with more certainty as well as with more force when it has but little, and that innocuous, fluid to act upon, rather than when that fluid has developed poisonous qualities which at the same time tend to paralyze its action and are themselves dangerous to the system through which they must pass before they can be finally eliminated.

Calomel in small doses, frequently repeated, has served us very well, but there is an advantage, of course, in using a saline purgative if possible. The presence of a saline fluid in the intestine of a higher specific gravity than that outside favors dialysis, and tartrate of soda in one- to two-drachm doses has proved very effectual, while free—in the writer's patients—from the risk of causing vomiting. Turpentine enemata assist; but the old-fashioned soap-and-water enema mixed with half an ounce of castor oil has been found the most effective of all. This has come to be relied upon as certain if used after two or three doses of the soda salt have been given. But, for the reasons insisted upon above, treatment is begun early.

*THE TREATMENT OF CERVICAL ADENITIS.*

In the *Boston Medical and Surgical Journal* of December 3, 1896, F. M. BRIGGS calls attention to a valuable method of treating this affection.

For a period of five years he has acted upon the theory that cervical adenitis is not a source of systemic infection, that the glands can be left *in situ* with perfect safety, and that their excision is called for only in exceptional cases. With every year, experience proves the soundness of this conclusion.

The first object of treatment in all cases of cervical adenitis is to bring about subsidence, by treatment of the cause if that is evident, by direct treatment of the gland itself if no cause is at hand. In chronic cases even where the cause can be clearly demonstrated, treatment must often be both general and local. As regards the use of drugs, this must depend upon the individual case: mercury, iodide of potassium for syphilis, iron for anemia, quinine, strychnine, nux vomica, calisaya, cinchona, malt, etc., or any proper combination of such drugs, as indicated. Cod-liver oil is surrounded by a time-honored halo; it is a question whether it has the specific action on these glands that it is supposed to have; it is indicated where the condition of the patient shows that fat is needed; one teaspoonful three times a day is enough for any adult, and a smaller quantity for a child.

As regards local treatment, the external use of tincture of iodine is often of great benefit, but it should be applied intermittently, not continuously. It should be painted on heavily for three or four days, then omitted until the skin has recovered, and again applied for three or four days. Even where there is no immediate apparent effect, Briggs continues its use in this way for a long time, and has seen subsidence occur in cases which he thought to be hopelessly chronic—whether as a result of treatment, or a coincidence, he is unable to say. Personally, he gives the benefit of the doubt to the iodine.

Contractile collodion, applied thickly, sometimes causes subsidence. It is indicated only where one or two glands are involved and where they are comparatively soft.

Injections of carbolic acid into the gland tissue is recommended, but as the author has never tried this method he can give no opinion as to its merits.

It would not be an overestimate to state that in fully ninety per cent. of all these

cases, we can expect one of two results, namely, subsidence or pus. Supposing, however, that in any given case subsidence does not occur, and no abscess results, but the indolent masses stay enlarged, with little or no change; should such glands be excised? The writer is strongly opposed to their removal until there is positively no further chance of a cure by absorption—that is to say, until the long-continued chronic inflammatory process has caused a true tissue change. But just when this time can be said to have been reached, is a very difficult point to decide. He makes it a rule that no such gland be removed until it has remained unchanged for twelve months. He emphasizes *unchanged*, for if during that time it has gone partially down, then enlarged again, he considers that there is still chance for absorption.

Excision of cervical glands is not a satisfactory operation. If only a few glands are to be removed at the time, others are liable to enlarge and call for one or more future operations; and if a whole chain, both superficial and deep, is involved, the removal is no slight matter, either at the time or afterwards.

In conclusion, there is left to be considered a very frequent result of cervical adenitis, namely, cervical abscess. Having already written twice at some length regarding the treatment of cervical abscess, with reference to the avoidance of scar, the writer only briefly recapitulates what he has published in previous articles.

Since his last report, made in May, 1895, in which he gave a table of thirteen cases, he has added to the list numerous other cases that he has treated; but as the results have been, with one exception, uniformly good, and similar in every way to the results already recorded, he adds no further notes. Out of some forty cases treated, he has had but two scarred necks. The almost invariable rule is either no scar, or a mark so slight as to be merely a blemish.

He has named his method the cannula treatment, and it is simple and satisfactory. His results are obtained by using a little self-retaining drainage cannula. The skin-cut is barely three-eighths of an inch in length, just long enough to admit the cannula, which upon being inserted is pushed in until its joint is reached; it is then reversed by closing its outer arms, when it is retained within the cavity, dilating the tissues in the vicinity of the cut and giving good drainage

through a minimum cut. It should be left in place from twenty-four to seventy-two hours, but usually two days are sufficient. The shorter the time it is left in, the better the result; and it is wiser to err in removing it too soon than to leave it in too long, for it can be reinserted easily at any time should further drainage be needed.

Syringing and curetting are not needed. Nothing should enter the abscess except the knife which opens it and the cannula which drains it. In the average case, healing follows in from five to seven days; but if the gland is only partially destroyed when pus is evident, the case may take many weeks. In these cases a persistent sinus is left, calling for treatment. It is here that injections and curetting are called for. He dilates these sinuses with olive-pointed bougies, scrapes with a small curette, and injects with any one of the various stimulating or irritating solutions, according to the apparent condition of the lining wall of the sinus. These cases are extremely tedious, but the final result is good.

---

*MASSAGE MOVEMENTS AND BANDAGING  
IN THE TREATMENT OF DIS-  
PLACED SEMILUNAR  
CARTILAGES.*

DOUGLAS GRAHAM, of Boston (*American Journal of the Medical Sciences*, November, 1896), quoting Allingham, states that the semilunar cartilages may slip forward, backward, inward, or outward. The internal semilunar cartilage is the one most often at fault.

As to the symptoms in general: The knee is usually semiflexed and cannot be extended; but flexion is usually free in recent cases. The foot is turned outward when the internal semilunar cartilage is displaced; inward when the external semilunar cartilage is displaced. In most cases little or nothing abnormal can be felt about the joint, except the position of semiflexion and a little tenderness at the head of the tibia. Rarely can the cartilage be felt projecting, and, even when it does, synovitis may supervene in a few hours and mask the symptoms.

As to the causes: Though any violent accident may produce internal derangement of the knee-joint, yet most cases would probably coincide with Dr. Knott's instructive description of his own case: "It has always been the result of a very slight, and in every instance an indirect, violence. This violence

has always been applied so as to produce a twist at the knee, either of the leg outward or of the femur inward. The most common cause has been striking the inside of the great toe against something when the knee has been slightly flexed, the parts about the joint as relaxed as possible, and the muscles thrown off their guard." He never suffered any derangement when the limb was in a decided state of active motion.

Scott Lang points out that the internal semilunar cartilage is displaced in rotation of the leg outward combined with flexion; the external semilunar cartilage in rotation of the leg inward combined with flexion; and that the injury is caused by some sudden and almost involuntary movement when the muscles governing the joint are off their guard or fail to act in concert with one another. A lax condition of the ligaments and muscles of the knee joint from general debility or previous synovitis would predispose to these accidents.

Laying aside cases that require surgical interference by cutting into the joint, the indications for treatment are very clear. Restore the cartilage to its natural position, if possible. Retain it there. Strengthen the joint and muscles so that they will be less likely to be caught off guard.

Various suggestions are made as to the methods to be pursued to replace the semilunar cartilage. When one fails, another is tried. A method that seems to be much relied upon is: Flex the leg as much as possible upon the thigh, then rotate the tibia inward if the inner cartilage is displaced, outward if the outer one is displaced, and extend the leg quickly upon the thigh while pressing with the thumb where the cartilage is supposed to be out of place. The opposite procedure—extension, then flexion with pressure—sometimes succeeds. As it may be very difficult to ascertain whether a cartilage has slipped out of place or not, Dr. Samuel J. Mixer has made the very shrewd suggestion that every case of sprain or twist of the knee should be put through the movements of replacing a dislocated meniscus. But if a semilunar cartilage is not displaced, it is very evident that such a procedure would hurt the patient unnecessarily and be very likely to aggravate a sprain of this joint, or even cause a displacement of the cartilage in a sprained knee.

With regard to the second indication, it does not appear that a ham-splint or a plaster cast is so direct and effectual in retaining a

semilunar cartilage and supporting and comforting the knee, as a pad with a snug bandage over the offending region. Moreover, there would seem in some cases, at least, to be a tendency of these cartilages to slip back into place even when attempts to readjust them had failed; but if the joint is immovably fixed by a ham-splint or plaster cast, its power to adapt itself to a return of the cartilage by gentle change of motion is prevented, which is not the case with a pad and bandage. For the relief of the heat, pain, and swelling that result from a sprain, wrench, or twist, massage properly applied is most satisfactory, while for the preservation of the circulation, nutrition of the muscles, and prevention of atrophy, it has proved quite effectual when applied early.

As displacements of the semilunar cartilages are most likely to occur when the muscles are off guard, so to speak, our endeavor should be to strengthen these muscles so that they will not be "caught napping." The behavior of the muscles in this manner is due in great measure to a loss of "muscular sense," the restoration of which is promoted in an astonishingly agreeable manner by means of massage, which at the same time helps to bring back the automatic action of will and spinal cord in presiding over these lazy sentinels. And this will be still further aided by alternating massage with carefully graduated movements of pushing and pulling, and of voluntary efforts at holding the leg extended. A few minutes' application of the faradic current to the quadriceps extensor muscles immediately after the massage sometimes seems to have a more invigorating effect than either alone, and, moreover, the contractions caused by the faradic current are but another and useful form of motion—semi-active, semi-passive.

Walking with the foot turned inward is considered to be a good precautionary measure when the internal semilunar cartilage is liable to slip out of place, with the foot turned out when the external cartilage is likely to slip, according to Scott Lang; but as either of these positions allows all the more latitude for rotation in the opposite direction when the knee is semiflexed, it can only be safe so long as the patient receives no violence to throw the leg in the opposite direction; whereas, if the patient walks with the foot turned out and the knee extended, where it is a question of preventing dislocation of the internal semilunar cartilage, then, as the knee is already in the position where

the cartilage is liable to be displaced, but with the muscles on guard, unexpected violence is resisted, and the range of dangerous motion is reduced to a minimum.

In cases that have required operation for the removal of the semilunar cartilage, or for stitching them in place, the joint is generally stiff for two or three weeks after the operation. Dr. Allingham recommends daily massage and passive motion, and later, that the patient try to sit on his heels. A much safer plan than the latter is for the patient to hold on to something, such as the mantel-shelf or the foot of a bed, so as to graduate and control the weight upon the knee.

Neither in their natural or their unnatural positions can semilunar cartilages often be distinguished from the surrounding tissues.

In cases requiring surgical operation, the treatment above indicated may be safely tried in some instances before cutting into the knee-joint, but more especially after operation for restoring motion and strength to the knee.

#### *A NEW METHOD OF RADICAL CURE OF INGUINAL HERNIA WITHOUT SUNKEN THREADS.*

An article in the *Semaine Médicale* of November 11, signed by Professors DUPLAY and CAZIN, illustrates a way in which the hernial sac may be tied without threads, which frequently produce trouble later. The sac is first opened and explored with the fingers, all adhesions detached, and a portion of the omentum resected if necessary. The sac is then completely dissected, and an assistant draws out the base with a pair of forceps as far and as long as possible, with that portion of the peritoneum normally situated two to three centimeters above the internal inguinal ring. The operator then seizes the end with another pair of forceps and draws it around and through to make a knot, as high up as possible; the ends remaining above the knot are then split and one end is drawn around and through in the same way, to make another knot, or passed through a slit in the other half, and this is repeated as often as the length of the sac will allow. In one case the sac was so short that it was split in four pieces and the four ends tied in knots, two by two. A strong fastening is thus made without the introduction of any foreign substance, remarkably simple and perfect in its results. When the traction ceases it sinks out of sight immediately, as in the classic operation. It was always found that the

highest part of the knot remained two or three centimeters above the internal inguinal ring. The operation is completed in the usual manner. If the sac is too thick to be tied in this way, it can be split and knots made in each half separately.—*Journal of the American Medical Association*, Dec. 26, 1896.

**REMOVAL OF TUMOR OF THE MESEN-  
TERY, RESECTION OF FORTY-FOUR  
INCHES OF INTESTINES, END-  
TO-END ANASTOMOSIS WITH  
MURPHY BUTTON.**

G. W. MASTON, in *The Medical Brief*, relates the case of a male, forty-nine years of age, who had noticed an enlargement in his abdomen for over three years, which had caused considerable discomfort. The tumor was movable, and a diagnosis of solid tumor of the mesentery, probably malignant abdominal, was made. The intestines were intimately attached to the growth.

Operation was decided upon. The tumor was hard, six inches in diameter at the widest point, two inches at the narrowest, and about two inches thick; it proved to be a spindle-cell sarcoma. Anastomosis was performed with a large-sized button, the upper end being put on a stretch when the button was *in situ*. The operation occupied one hour and left the patient with a good pulse. Following the operation liquid food only was given for twenty days.

Considerable lancinating pain in the abdomen was complained of, and four months after the operation much borborygmus was felt; the stools were thin and ashen-hued. The patient died in great pain five months after the operation.

Post-mortem disclosed the intestine united for about three-fourths of its circumference, with an ununited portion at the mesenteric border; the button had lodged about six inches below the point of approximation, and produced perforation. There was no contraction of the gut at the point of union.

**A NEW METHOD OF TREATING STRIC-  
TURE OF THE RECTUM.**

BACON, in *Mathews' Medical Quarterly*, proposes the method given below in strictures of the rectum. In January, 1895, this author published a method for stricture which consisted of a plastic operation, using the sigmoid flexure to form a new channel around the strictured portion of the canal, and

claimed it was a sure means of relieving all non-malignant strictures of the rectum located above the levator ani muscle; but for that class of strictures located just above the internal sphincter ani, no plastic operation can be done that will give fecal continence afterward. These strictures have been unsuccessfully treated for ages by various methods, such as gradual dilatation with bougies, forcible divulsion, internal and complete proctotomy, and later by means of electrolysis; they cannot be dissected out and the ends of the bowel united without leaving a circular cicatrix that will reform another stricture of the gut.

Complete proctotomy gives temporary relief by severing the stricture band, but the wound soon fills up with granulation tissue that reforms fibrous tissue, and the stricture is worse than before operation was done. Then, again, in making the complete proctotomy the sphincter muscles are severed, and often do not unite perfectly, and incontinence results. Bacon has successfully tried his present method and found that it does not interfere with the sphincter muscles, yet accomplishes permanently what complete proctotomy only does temporarily. The wound made by a complete proctotomy—that is, when an incision is made, beginning with the rectum and cutting through the stricture band back to the coccyx and sphincter muscles—is the shape of a letter V after the ends of the stricture retract.

If we can prevent this triangle from filling up with fibrous tissue, the severed stricture band must disappear by absorption. In order to accomplish this the author produces a mucous fistula between the stricture and the coccyx, so that after the proctotomy is made the mucous tract will be at the bottom of the wound and prevent the union of the severed stricture bands.

The operation is simple and quickly done, and practically free from danger. The patient having been thoroughly anesthetized, the operator takes a blunt-pointed aneurismal needle, threaded with a very heavy silk ligature, and at a point just above the internal sphincter on the posterior rectal wall in the median line punctures the gut and carries the needle point well back into the perirectal tissue to the coccyx, and up behind the stricture above the upper limit, when the needle is forced through the rectal wall into the rectum. The ligature is now seized with a blunt hook or dressing forceps, and one end drawn down through the stricture opening, and the

needle withdrawn. The two ends of the seton are now securely tied, and left hanging outside the anus. The loop of thread is left long so as to avoid severing the stricture, as it is necessary to have the seton in place for about three months to get a continuous mucous tract. There is practically no pain following the operation if the thread is tied outside of the anus and a loose loop left. Out of eighteen cases there has been no infection from the ligature or abscess, as the drainage is complete. At the end of three months the patient is again anesthetized and the seton withdrawn; a grooved director is passed through the fistulous tract behind the stricture, and the intervening stricture band severed with a Paquelin cautery. The patient is kept in bed one week after the seton is inserted, and again one week when the stricture is divided. For two weeks after each operation the bowel is irrigated daily with solution of boracic acid.

The writer reports three failures, which he believes due to not taking in more tissue above and below the stricture band, so as to catch all the scar tissue above and below the real constriction.

#### THE BETTER OPERATION FOR HEMORRHOIDS.

VAUX (*The Canadian Practitioner*, December, 1896), Resident Assistant of Mt. Sinai Hospital, New York, describes the routine treatment in that institution as follows:

On admission the patient is given a bath, and if hemorrhoids are strangulated an ice-bag is applied to anus; should they be merely smarting and inflamed, a wet Thiersch dressing is applied. The night preceding operation the patient is given a half-ounce of compound licorice powder, and at 5 A.M. a high enema, followed by a low one at 7 A.M.; if necessary these are repeated, the test being that the fluid comes away absolutely clear. No food is given on the day of operation. The perineum is shaved in the ward, but the scrubbing up of the patient is in the operating room. When the patient is anesthetized, the first assistant dilates the sphincter and thoroughly cleans the rectum with soap and water, by means of a sponge and holder, and then it is irrigated; the perineum and thigh are scrubbed with soap and water, followed by ether and bichloride of mercury; wet bichloride towels are laid over the pubes and around the field of operation. Absolute antiseptic precautions are observed, the prep-

aration of hands being the usual form for operations, and all instruments most carefully sterilized. There is no room in Mt. Sinai for the idea that the rectum is dirty, and therefore hands and instruments may be dirty too; as a consequence, sloughing or pyemia is almost unknown. A good-sized sponge with string attached is wrung out of bichloride and introduced high into the rectum, and the assistant, grasping the string, makes sufficient traction to protrude the internal piles.

The technique of the operation may be summarized under three headings:

1. Apply the clamp in the long axis of the hemorrhoid so that the scar may be a radiating one, and thus avoid any chance of cicatricial stenosis.
2. Dip the distal end of the clamp well down, so as to include the mucous membrane of the hemorrhoid in its entire length, though only clamping off about one-third of its substance. Be sure that no skin is included, otherwise the subsequent edema will be very great and time of recovery lengthened.
3. Sear the hemorrhoid slowly from above downward, layer by layer, the cautery being only at a dull red heat; by observing these precautions any subsequent hemorrhage is avoided.

4. Insert a tampon cannula as described below, which must not be removed till expelled by the first stool.

When the anesthesia wears off the pain will be intense, and opiates must be given. At 5 A.M. on the morning of the third day a half-ounce of magnesium sulphate is given, and at 7 A.M. an oil enema is administered through the tampon cannula; this is important, as it saves much pain when the tampon is expelled. The enema being expelled brings the cannula with it, and the first stool is comparatively painless. On each succeeding morning a half-ounce of magnesium sulphate is given, and on the fifth day the edema will have disappeared in great part, and by the eighth day patient is ready to go. No dressing save a piece of iodoform gauze and a T-binder is used. In a ligature operation the bowels are moved on the fourth day, and in a Whitehead on the fifth.

The tampon cannula mentioned above is made by taking a piece of half-inch rubber tubing, sterilizing it, and wrapping around it several layers of iodoform gauze; it is then anointed with sterilized vaselin, and after the operation, is inserted in the rectum. The tampon cannula serves a double purpose: it

allows the escape of secretions and flatus, so that all danger of retained hemorrhage is avoided; and also allows the primary enemas to be given without much pain.

In conclusion, he reviews the advantages of the clamp and cautery: It is antiseptic; not only can the clamp be readily sterilized, but the cautery itself is the most powerful germicide; there are no sloughs to separate as in the ligature operation; there are no ligatures or sutures to offer any chance for infection; it is a radical cure; the operation is a rapid one; the time of convalescence can be definitely fixed—the eighth day. The operation, which was formerly but little employed, is now in high favor in the New York hospitals. The record of hemorrhage, pyemia, or death is almost negative. In five hundred cases operated upon in Mt. Sinai, by the above method, there has not been a single death. One case of pyemia from which the patient recovered is recorded, and a few slight hemorrhages; and, so far as can be ascertained, there have been no recurrences.

#### PREVENTION OF FOLLICULAR TONSILLITIS.

MAXSON (*Journal of Practical Medicine*, December, 1896) states that prevention of follicular tonsillitis is desirable in at least two classes of cases: those occurring during an epidemic, and those where there are repeated attacks occurring from once a month to once a year. Those occurring only during an epidemic can be prevented by a mild antiseptic throat wash, with or without the internal administration of benzoate of soda. The chronic cases, which are subject to frequent and repeated attacks, are very annoying to the physician and damaging to the patient's health. Such has been his experience until he applied a treatment that he has lately found, known and used by others, but which is not mentioned in any literature that he has access to. The treatment consists in destroying the contents of each follicle that is diseased in both tonsils. He does not think that the follicles themselves, but only the colonies of germs that make an abiding place therein, are destroyed.

It is the writer's custom to take a doubled piece of silver wire, such as is used for sutures, and solder its free ends to a large wire; then dip the doubled silver loop into melted nitrate of silver, so as to make a small bead on its end, after withdrawing it from the melted silver salt. The silver wire is then

bent half an inch from its distal end, so as to make an angle of forty-five degrees. This bead of caustic is inserted into each follicle to its bottom; the depth will vary from one-fourth to one-half an inch. One caustic bead will usually treat from one to two follicles. By means of several beads all the follicles may be treated. This treatment is undertaken at any time except when the tonsils are acutely inflamed. It requires one or two treatments effectually to prevent its return. He has used this treatment for eight or ten years, and found it entirely reliable, and knows of no case that has not been given a very complete immunity even when subject to attacks every two to eight weeks before the treatment.

#### EUCAINE HYDROCHLORATE AS A LOCAL ANESTHETIC.

G. W. SPENCER, in the *Medical and Surgical Reporter* of November 28, 1896, presents further evidence in regard to the action of eucaine as an anesthetic. He believes it is a valuable addition to our resources; it is rapid in action, safe, produces positive and prolonged anesthesia, causes no serious after-effects, and can be rendered aseptic by boiling; it is the best local anesthetic before the profession.

In the nose, throat, and eyes, eucaine has given great satisfaction, and operations upon these parts can be performed without a particle of pain. In operating upon these regions solutions similar in strength to those of cocaine may be employed, but we use a much greater amount of solution of eucaine than of solution of cocaine. There is not much difference as regards the rapidity, intensity and duration of the anesthesia caused by each of these agents. The greatest difference between cocaine and eucaine is that eucaine can be administered in large doses without danger, while corresponding doses of cocaine would put the patient in deadly peril. Cocaine in the hands of not a few, given in very small doses, has caused marked symptoms of poisoning.

Dr. Spencer then details twenty-four cases in which eucaine was employed. The technique consisted in making an incision over the median line and in the long axis of the trachea. This incision extended from the upper border of the cricoid cartilage, downward for two inches; it divided the skin and superficial fascia. The anterior layer of the cervical fascia was then incised, and the

sterno-thyroid and the sterno-hyoid muscles were separated. In each case the isthmus of the thyroid gland extended well up on the trachea, and it was found necessary to incise the fascia which invested it in order to expose the trachea. The said fascia was incised by a transverse incision at the upper border of the cricoid cartilage, and this allowed the isthmus to be lifted and pushed downward. In each case three rings were incised and a tracheotomy tube was inserted. The operation in each case lasted about twenty minutes, and anesthesia was complete throughout.

An analysis of the twenty-four cases mentioned will probably convince the reader that in eucaine we have an agent which is safe and reliable. Three cases are considered major operations, and while ten were not so considered, they were such as ordinarily require the use of a systemic anesthetic to permit of operation. The operation in four cases was greatly facilitated by using a drug that induced anesthesia, but which allowed the trachea to be controlled by the patient. With anesthesia by eucaine these patients are conscious and can keep the trachea still during critical stages of the operation; in anesthesia from a systemic anesthetic, mucus accumulates in the lungs and stomach, and efforts at expulsion keep the trachea constantly in motion, which movement greatly interferes with the operation. Chloroform and ether irritate the lungs and predispose the patient to acute bronchitis and pneumonia. Tracheotomy itself is a predisposing factor in pneumonia.

Taking these facts into consideration, it is well to select an agent to allow of a painless operation, which will not affect the respiratory organs injuriously while operating in their locality. No pulmonary symptoms followed the use of eucaine in any of the above cases. One case had mitral regurgitation; two drachms of a five-per-cent. solution had no effect on the circulation. Another case had an irritable heart, and she was very nervous; two drachms of a five-per-cent. solution acted as a sedative to her condition.

One case had a pint of pus in the left pleural cavity; this naturally deprived the heart of a portion of its space. Two drachms of a five-per-cent. solution had no effect on the circulation or respiration. The average duration of anesthesia from eucaine is about twenty minutes; the time to wait for complete anesthesia is five minutes. Two drachms of a five-per-cent solution used hypodermic-

ally will in the majority of cases be sufficient to induce anesthesia; but larger amounts can be employed if necessary. The number of sutures used in the operations were ninety-three. After using and seeing sutures employed in so many cases, the author does not agree with the assertion made by Fuller that eucaine exerts a hardening action on the tissues.

#### *HYSTERECTOMY BY COMBINED ABDOMINAL AND VAGINAL OPERATION.*

PENROSE (*American Journal of Obstetrics*, December, 1896) states that for the past year he has been performing complete hysterectomy for cancer by a combined method of operation through the abdomen and vagina. In the combined operation as usually performed, the vaginal part of the operation is done first, the abdominal part last.

In the method of operating which he followed he has begun through the abdomen and finished the operation by way of the vagina. This method seems to present several distinct advantages. The following is the technique: The abdomen is first opened; the ovarian arteries and the round ligaments are secured by ligatures; the broad ligament is divided down to the level of the internal os, and the bladder is dissected from the anterior face of the uterus and the upper portion of the vagina; a small gauze pad is then inserted in the space between the bladder and the upper portion of the anterior vaginal wall; a similar pad is inserted at the bottom of Douglas' pouch, immediately behind the upper portion of the posterior vaginal wall; the abdominal incision is then closed; the woman is placed in the dorso-sacral position; the cervix is exposed through the Sims speculum; the posterior vaginal fornix and the anterior vaginal fornix are opened by incisions made directly over the gauze pads—the incision may be made boldly and quickly, because the pads prevent intestinal injury; the vaginal mucous membrane is then divided on the sides of the cervix, and the bases of the broad ligaments are secured with large forceps; the uterus is then cut away, and removed through the vagina; the gauze pads are withdrawn and the vagina is packed with gauze.

The advantages which this method of combined operation possesses over the operation which is usually performed, of entering the vagina first and finishing through the abdomen, are the following: The dirty part of the operation is done last; the septic cervix is

withdrawn through the vagina and not through the peritoneal cavity; the vaginal part of the operation is facilitated by the preliminary separation of adhesions in the upper part of the pelvis, by the division of the upper portions of the broad ligaments, and by the dissection of the bladder from the uterus, this operation being easier from above than by way of the vagina.

The operation seems also to possess some points of advantage over the operation of complete hysterectomy from above as it is usually performed to-day. In complete hysterectomy the vaginal vault is either closed by suture after the uterus has been removed, or, more usually, the safer method is followed of leaving the vaginal vault open and draining by gauze through the vagina. If the latter method is employed there is usually infection of the ligatures which secure the uterine arteries, with resulting persisting sinuses. This difficulty is, of course, avoided by the use of catgut ligatures.

Again, when the vaginal vault is opened from above the operator cannot determine with certainty that the incision is made outside of all infiltrated tissue, and in case of cancer of the cervix it is frequently necessary to excise a portion of the vagina after the uterus has been cut away. This is contrary to the sound surgical advice, to remove cancerous tissue in one mass when possible.

---

#### INGUINAL ORCHEOTOMY: A NEW METHOD.

*The Lancet* of December 12, 1896, contains a paper by HANDLEY in which he advocates the following procedures:

He prefaces the description of his method by the statement that standard books on operative surgery recommend an incision extending from a point just below the external ring to the bottom of the scrotum; the object of this long incision is to ensure free drainage of the abundant cellular tissue of the scrotum, in which hemorrhage is so likely to occur. It must be admitted that a collection of disintegrating blood-clots in this region may be a source of intense septic poisoning. It can be shown, however, that this long scrotal incision produces those very evils which it is designed to prevent. In the first place, it gratuitously involves cutting through a large extent of the vascular subcutaneous tissue of the scrotum, and thus directly conduces to hemorrhage after the operation, with its accompanying evils. Hav-

ing produced the hemorrhage, the incision provides a ready entrance for septic organisms; this is partly due to the contractility of the scrotal skin, which makes accurate apposition of the edges an impossibility, partly to the difficulty of keeping a dressing securely applied to the scrotum, and partly to the septic character of the surrounding region of the skin. Moreover, any urine which escapes will drain downwards into the wound. It will be seen that the conditions for the production of suppuration are almost ideal, and, indeed, the after-progress of castration wounds is at present notoriously unsatisfactory.

The method Handley advocates—which he terms the inguinal, as distinguished from the present or scrotal method—avoids all these evils; it is based on the principle that all interference with the scrotal tissues during the operation is dangerous and unnecessary. An incision of from one inch to one and a half inches long, and slightly curved, with its concavity looking downwards and outwards, is made over the external abdominal ring in the line of the spermatic cord. The cord is exposed and isolated; it is then seized with the fingers of the left hand and pulled gently upwards. With a blunt dissector the subcutaneous tissue is freed, first from the lower part of the cord, and then from the testicle as it appears in the wound, the left hand keeping up gentle traction on the cord while this is being done. The testicle is delivered through the small incision and the cord dealt with in the usual manner. Afterwards the scrotum is invaginated through the wounds in order to inspect the bed of the testicle for bleeding points, which in the two cases he has operated on were conspicuous by their absence. The incision is then closed by a continuous horsehair suture.

This method has many advantages over the scrotal method of castration. The short incision passes through the firm cellular tissue over the external ring, and the testicle is shelled out without any disturbance of the loose vascular tissue of the scrotum. The slightness of the vascular connection between the testicle and its bed is shown by the frequency with which it appears in the wound during the operation for the cure of inguinal hernia; hence the risk of hemorrhage into the tissues after castration is done away with. Owing to the absence of dartos the edges of the incision can be accurately brought together, and in forty-eight hours the risk of infection from without is past.

The delayed union so common in scrotal incisions is avoided. It may be well to include the scrotum in the dressing, pulling it upwards and forwards; should it, however, slip down on the perineum, the incision will still be well covered by the dressing. If it is thought preferable a sealed dressing may be applied immediately after the operation. Any sealed dressing applied to the scrotum itself would certainly become loosened by the darts within a few hours, but on the smooth skin over the external ring it may be relied on to keep firm and close. Should any dribbling of urine occur, the incision is well above the end of the penis instead of being immediately underneath it, and is thus much less likely to get wet. Finally, though this point is unimportant, the time of the operation is shortened, because there is less trouble with bleeding, and the incision can be more quickly sewn up. In the two cases on which, by the kindness of Mr. R. Clement Lucas, he has had the opportunity of trying this method, healing took place by primary union without rise of temperature or other complication. The long scrotal incision appears to be a relic of the time when surgeons recognized that their wounds must of necessity become foul cesspools, to be drained and cleared out on ordinary sanitary principles. A scrotal incision is only necessary when the testicle is much enlarged, or adherent to the skin.

#### CLEANSING AND CLEANLINESS IN ABDOMINAL SURGICAL OPERATIONS.

LAWSON TAIT (*Medical Record*, Dec. 19, 1896), in an interesting paper on the above subject, gives the following directions: First of all, if an operation such as the removal of an ovarian tumor has been conducted so well and so fortunately that nothing has entered the peritoneal cavity, the wound ought to be closed at once without sponge or anything else entering it. If, on the contrary, a mess has been made inside, it must be cleaned out; and the question is to decide on the best method, and the weight of argument should always be against the use of sponges—they are so inherently dangerous. Yet their use is often essential; thus, in separating adhesions of the omentum to a tumor nothing displays the ability and dexterity of a surgeon so much as the rapid folding up of a dry sponge in the damaged apron; or, if the adhesion of the appendages to the pelvic wall bleed freely, the pelvis must be packed, and the packing will probably remove much

dirt with it. Until two years ago the author always used sponges for this purpose, and would often have six or eight sponges squeezed tight down in the pelvis; now he uses iodoform gauze for this purpose. Who it was who led us to make this important advance he does not know; but it is one of real value, for iodoform gauze stops oozing from parietal and visceral surfaces in a way that nothing else will do, save perchloride of iron. If, however, a ligature has cut through a rotten parietal, or a vessel has escaped the forceps and ligature and cannot be found, washing out with a stream of clean water will speedily display the source of the bleeding and enable the vessel to be secured. He does not combine the two processes if he can help it, for they do not generally aid one another.

As Tait believes that pus is a substance already dead and generally decomposing, he takes the utmost care to cleanse it all away, or anything which from his view more or less imitates it, such as loose blood-clot and blood in solution. The method to be employed in this case is the continuous stream; the best way to serve this purpose is simply to reverse a stream of common tepid water through one of his ovariectomy trocars, and he uses a large one if he wishes to dislodge and wash out loose clots by means of a large volume of water issuing from a large tube; or, on the other hand, if he wants to wash carefully every inch of the peritoneal surface, he uses a small tube with a gently flowing stream. If the tubes are not handy—and in our worst emergencies, like ruptured pregnancy, they may not be—a very efficient substitute is to open the wound as widely as possible, pull up the parietals, and pour in with cautious violence one or more jugfuls of tepid water, insert the right hand into the abdomen, and with the left close the wound round the wrist as closely as possible. The process of washing may then be carried out as fully as is considered desirable. If a tube of the Tait pattern can be obtained, it is better to use it, for it can be carried into every one of the complex interstices of the peritoneum, and the washing be thereby made most thoroughly; but the inexperienced operator should be cautioned against using a double tube for entrance and exit, as has recently been recommended. This is no new proposal, and when such is used the stream does not get spread but returns at once, short-circuited, as the electricians say, and without doing much cleansing. Care must be used to have the temperature of the water not lower than 100°

F., and not higher than 103° F., and it must be borne in mind that few women, and none of the nurse type, have any sense of temperature in their hands. To them, "blood heat" may be anything between 75° and 120° F.

The further or secondary cleansing of the peritoneum is secured by the use of the drainage tube, to be considered at length in another chapter.

#### SOME AFFECTIONS OF THE FEMALE BLADDER.

GARCEAU (*Boston Medical and Surgical Journal*, Sept. 10, 1896), in an instructive discussion of this subject, sums up as follows: Out of the forty-three cases, thirty-three, or seventy-six per cent., had had previous bladder trouble. This shows the frequency of vesical irritation in pelvic diseases. Of the ten cases in which there was no previous bladder trouble, the catheter was required in four; no irritation followed. Of the thirty-three cases, in twenty-four the catheter was used. Looking at the twenty-two cases in which no trouble followed operation, we find ten in which the catheter was used. This is certainly evidence that the catheter does not cause irritation. Looking now at the other twenty-one cases, we find the catheter was used in fourteen; they were either better or no worse of their irritation after operation, with the exception of six, and these six all suffered severely from bladder irritability before operation. It seems to be a fair conclusion, therefore, that the catheter, when properly used, has no effect in causing vesical disturbance, and that it will be found that those who have vesical irritability after operation had it before. It is not argued that the catheter does not cause infection when improperly used; in three cases out of the forty-three a distinct history of infection was obtained, dating in all three from retention of urine after confinement, the catheter being used.

The treatment of cases of vesical hyperemia is very unsatisfactory at times. Attention to the general health is of paramount importance. Digestion should be attended to, and, above all, the bowels should be kept freely moving in order to relieve the pelvic congestion as much as possible. It is needless to say that any coexisting pelvic disease should receive appropriate treatment. Local applications of nitrate of silver, and in some instances of glycerite of tannin and ichthyol, have been distinctly beneficial. Great relief

will be given by the use of the fine coil of the faradic current; here the bipolar vaginal electrode may be used, or one electrode may be placed over the bladder on the abdomen and the other in the vagina. In one patient this treatment was always followed by a good night's rest. If the urine is abnormal, this should be corrected. The various diuretics and vesical sedatives have been tried, but the results have not been remarkable.

Finally, if the patient continues to suffer, absolute rest in bed, with mild, unstimulating diet, must be insisted upon. This measure will nearly always be productive of good results. If it fails and the trouble continues, the question of artificial vesico-vaginal fistula is presented for consideration. The immediate relief given by this measure is most grateful to the patient; the very night of the operation she sleeps soundly, and wakes up refreshed in the morning. The urine drains away through the vagina, and gives a much-needed rest to the irritable sphincter. The woman quickly recovers her lost nervous tone, is more placid and peaceful, and is not harassed by the continual desire to urinate which made life a perpetual torment. The fistula must be left open a sufficiently long time—in cases of cystitis, until the pyuria has entirely disappeared. Another point to be emphasized is that the fistula must be made close to the sphincter; for if made high up near the cervix the urine will pocket below it, and so the operation fail because the irritation is kept up as before, the drainage being imperfect.

Pregnancy need not be considered a contraindication to this operation; on the contrary, the occurrence of pregnancy may so intensify the symptoms from the increased hyperemia as to render the operation imperative. This was so in one case of cystitis, in which a vesico-vaginal fistula was made. The patient's sufferings were intense, and she insisted upon having relief. The operation was entirely successful, and the pregnancy (three months) was not disturbed.

In conclusion, a word may be said about the method of making examinations of the bladder. The most comfortable position for the patient is the dorsal; the examiner also will find it easier to work with the woman in this position. In the knee-chest position the ureteral orifices are more prominent, but if the examiner is near-sighted he will find it rather difficult to get close enough to examine properly, on account of the cramped position he is obliged to assume. If ether be given,

the dorsal position will be chosen for obvious reasons. Ordinary daylight, with or without sun, gives ample illumination; the table should be placed close to a window, however, in order to have the light as strong as possible. If artificial light be chosen, a good strong gas-light must be used—preferably an Argand burner; the greatest care must be exercised not to burn the skin in case ether is used—this is an accident that easily happens, and the burns are most annoying and may be very serious. If the ureter is to be catheterized, the best place for the light, if gas, is at the side of the woman which corresponds to the ureter to be examined, and not on the abdomen. The examiner stands not in front of the woman, but on the side opposite to the light; if he examines the left ureter, the light is on the woman's left side and he stands on her right. This brings the ureteral opening directly in line with the light and the examiner's eye, and avoids cramped positions; the illumination is much better, as the light is reflected directly and not at an angle. For this idea I am indebted to Dr. Edward Reynolds, who was the first to suggest it. The examination is made much easier by means of it.

---

## Reviews.

---

**THE PRINCIPLES OF THEORETICAL CHEMISTRY.** With Special Reference to the Constitution of Chemical Compounds. By Ira Remsen. Fifth Edition, thoroughly revised.

New York and Philadelphia: Lea Bros. & Co., 1896.

The fact that Professor Remsen is one of the leading chemical authorities of the United States, renders anything which he may publish worthy of purchase by those who are interested in chemistry. This little manual is the clearest exposition that we know of which deals with chemical constitution, and it is fortunate for American students that they have placed in their hands such a lucid description of what to some persons proves a difficult subject of study.

**DISEASES OF THE STOMACH.** A Text-book for Practitioners and Students. By Max Einhorn, M.D.

New York: William Wood & Co., 1896.

Within the last few years the study of diseases of the stomach upon a rational and scientific basis has made extraordinary advances, chiefly through the work of German clinicians; although American and French investigators have followed not far behind their distinguished Teutonic leaders. Of these, perhaps the first are Ewald in Ger-

many and Einhorn in America. The numerous original contributions which Einhorn has made to this subject render him quite equal to the task of compiling the volume of nearly five hundred pages which we now review.

The book is copiously illustrated, describes all the more recent tests and methods of examining the stomach and its contents, and almost every page has its statements fortified by copious bibliographical references. The author is also careful to give full credit to American investigators in this field, and speaks in terms of high praise of the work of Dr. D. D. Stewart, of Philadelphia, whose name is already familiar to the readers of the **THERAPEUTIC GAZETTE**.

We bespeak for Dr. Einhorn's little manual the enthusiastic reception which it deserves.

**ARTIFICIAL ANESTHESIA.** A Manual of Anesthetic Agents. By Lawrence Turnbull, M.D., Ph.G. Fourth Edition, revised and enlarged. Illustrated.

Philadelphia: P. Blakiston, Son & Co., 1896.

In the preface to this fourth edition of Dr. Turnbull's well known book he tells us that he examined all the important works published since the third edition appeared, and many of the forms of apparatus which have been modified or recently introduced. He has also taken pains while abroad to study the methods of administering chloroform in Scotland. The result of this renewed study is to confirm him in the belief that ether is by long odds a safer anesthetic than chloroform, and he expresses regret that Wood, Da Costa and Carter have attempted to show that ether is more dangerous than we have heretofore thought it.

The book contains a large amount of useful and valuable information.

**PTOMAINES, LEUCOMAINES, TOXINES AND ANTITOXINES: OR THE CHEMICAL FACTORS IN THE CAUSATION OF DISEASE.** By Victor C. Vaughan, M.D., Ph.D., and Frederick G. Novy, B.Sc., M.D. Third Edition, revised and enlarged.

Philadelphia and New York: Lea Brothers & Co., 1896.

Those who are familiar with the earlier editions of this book will note that the authors have made a distinct addition and innovation in discussing, besides the ptomaines and leucomaines, the even more interesting subject of toxins and antitoxins.

The volume at the present time gives perhaps as complete a summary of what we know concerning these interesting subjects as can be found in any language, and certainly it affords the best which has appeared in the English language. Although the subject of ptomaines and leucomaines would not

at first glance seem interesting to the practitioner, the wide popularity of the earlier editions has rapidly exhausted them, and has shown that the profession in general appreciate such a summary of scientific progress and record of original work.

THE DISEASES OF THE MALE URETHRA. By R. W. Stewart, M.D., M.R.C.S.  
New York: William Wood & Co., 1896.

Many members of the medical profession—practically all who are especially interested in genito-urinary surgery—are familiar with the admirable articles which Dr. Stewart has published from time to time dealing with urethral surgery. It is with considerable pleasure that we welcome a book from the pen of this original and gifted writer.

The book opens with a chapter devoted to the anatomy of the male urethra, after which follows a discussion of Urethritis. This is classed as acute and chronic, and anterior and posterior. In regard to posterior urethritis he writes as follows:

"There is at the present time a growing tendency to the belief that acute posterior urethritis is such a common concomitant of acute anterior urethritis that it should be considered exceptional when it does not accompany the latter disease. The advocates of this theory claim that the disease is often overlooked and the frequency of its occurrence much underestimated, and also that it appears much earlier in the course of acute anterior urethritis than has generally been supposed. Statistics have been given to show that in eighty per cent. of cases of acute anterior urethritis a posterior urethritis is also present. . . . I am perfectly willing, as will be shown later, to concede the frequency of chronic posterior urethritis, but neither the experience I have had, nor the investigations I have made, warrant me in entertaining the belief that this disease is nearly as frequent a sequence of acute anterior urethritis as is indicated above. If we believe that infection of the deeper portions of the urethra takes place through the medium of the lymphatics, then we can readily conceive that the posterior urethra would rarely escape infection; but believing in neither, I must hold that acute posterior urethritis should be regarded as a complication, not as an essential part of a gonorrhea. In fact it must be considered the most serious complication liable to arise in the course of acute anterior urethritis, since it is a necessary forerunner of gonorrheal epididymitis, cystitis and pyelitis."

As to the diagnosis of acute urethritis, he states that we have settled back to the comfortable position of relying chiefly upon clinical symptoms, except when a clinical diagnosis is difficult or impossible. It is unfortunate that Stewart lends the weight of his influence to this teaching, since with the exception of a small coterie in this country it is probable that specialists the world over are relying more and more absolutely upon microscopic examination, not only for diagnosis, but as a means of directing their treatment.

The irrigation treatment is, he holds, disappointing, and injections are not advised until the period of decline of gonorrhea.

There is one paragraph with which all men of judgment and experience will heartily agree. Stewart states: "The cure of gonorrhea is often delayed by overanxiety or overactivity in its treatment, and it will often progress more favorably if permitted for a time to pursue its own course toward recovery." The section upon Stricture, though concise, is particularly clear, original and forceful, and can be commended without reservation.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. In Photo-lithochromes from Models in the Museum of the Saint Louis Hospital, Paris: with Explanatory Woodcuts and Text. Parts V and VI. By Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Feulard, and L. Jacquet. Edited and Annotated by J. J. Pringle, M.B., F.R.C.P.

London: The Rebman Publishing Co., Ltd. Philadelphia: W. B. Saunders. 1896.

The GAZETTE has already stated its opinion of the manner in which authors and publishers have cooperated to produce an Atlas of Skin Diseases which bids fair to rival all its predecessors.

Part V contains photo-lithochromes with brief clinical descriptions of Conglomerative Tricophytic Folliculitis, Lupus Pernio, Papulo-tuberculous Syphilides, Vacciniform Infantile Ecthyma, together with a number of woodcuts.

Part VI contains photo-lithochrome plates of Ulcers and Scars in an Habitual Cocaine Consumer, Tricophylosis of the Skin, Syphilitic Hyperkeratosis, Psoriasis Figurata. The text accompanying these beautiful pictures is particularly clear.

THE SURGERY OF THE CHEST. By Stephen Paget, M.A. Oxon., F.R.C.S. Illustrated.  
New York: E. B. Treat, 1897.

In this work, the only one of its kind, the author has embodied the results of the accumulative records of thoracic intervention, to-

gether with those of his own personal experience. The first chapter is devoted to Landmarks of the Chest and General Malformations. Concussion and Contusion are next considered. In regard to concussion the author has no explanation to advance for the severe or even fatal shock which sometimes follows a comparatively slight trauma of the chest. The treatment is that applicable to shock. In the chapter devoted to Fractures and Dislocations of Ribs, Costal Cartilages, and Sternum, special attention is devoted to costal fracture in the insane. Paget states that the weight of evidence seems to be against the occurrence in the ribs of the insane of any definite changes directly due to insanity. Complications of fracture and internal injuries are considered at length, including trauma of the Lungs, Blood-vessels, Pleura, and Heart. Chapters are devoted to Emphysema, Pneumothorax, Hernia of the Lung, Wounds of Intercostal and Internal Mammary Arteries, and Hemothorax. It is stated that the intercostal arteries are rarely wounded in the operation for empyema; two cases are reported. Dulac by cadaveric experiments found that this artery may be readily wounded by an incision close to the lower border of the upper rib, either in the sixth, seventh, or eighth space, alike in the anterior, lateral, or posterior part of the chest.

A number of cases of wound of the intercostal artery are quoted.

In treating wounds of the lung he quotes as applicable what Rose says of wounds in the region of the heart:

"Certainly the worst thing of all for the patient is 'thorough examination.' We have got past that bad time in surgery, when a man would not leave a fractured pelvis alone till he had made it crack, or, as he called it to pacify the patient, till he had established beyond doubt the presence of crepitation. Why should we treat cases of internal wound or injury worse than we now treat a fractured pelvis? In all such cases I avoid all repeated examinations; I make the examination with all gentleness; I never probe the wound or put my finger in it; I percuss the patient softly, do not ask him to breathe hard during auscultation, and prefer not to listen to his back, rather than set him up in bed without some special reason, or disturb by any movement the delicate half-formed adhesions, which are our chief hope of his recovery. But there are still cases where, in spite of all my warnings and orders, these rules are broken, and the excessive zeal of some of my

assistants for accurate diagnosis has retarded healing and brought the patient into grave danger of death."

Cases in point follow. General Operative Treatment is briefly considered; Wounds of the Heart are dealt with at length; then follow Wounds of the Diaphragm and Diaphragmatic Hernia.

The second portion of the book is devoted to Diseases of the Chest and has to do with affections of the Bones, with Tumors, Pleural Effusions, Abscesses of the Lung, Gangrene, Phthisis, Diseases of the Bronchial Glands, and Foreign Bodies in the Air Passages. To the Surgery of the Heart is devoted a special chapter. Finally, Subphrenic Abscess and Operation through the Pleura for Hydatid Cysts of the Liver are considered.

The Appendix includes Reclus' Address upon Thoracic Surgery and Bulow's Treatment of Empyema by Continuous Syphon Drainage.

There can be no question as to the value of this book nor as to the skill with which the disseminated reports in modern surgical literature which bear upon the subject considered have been utilized in the formulation of sound conclusions. The book is one so valuable to the surgeon that he should not be without it.

### *LONDON LETTER.*

BY ST. CLAIR THOMSON, M.D., M.R.C.P., F.R.C.S.

The New Year has opened auspiciously for the profession in this country. The first news which greeted us on the 1st of January was that Sir Joseph Lister had been made a peer. This is the first time that a medical man has been given a seat in the House of Lords; we may therefore be excused for looking on it as an epoch-making occurrence in the social history of medicine. For Lord Lister himself one does not stop to even view the event as an "honor;" the government honors itself in bestowing the title. It is the whole profession which is to be congratulated on this public recognition of one of its members. At the same time one cannot quite get away from a feeling that Lord Lister's peerage has not been entirely bestowed for his professional eminence; had it been so, it should have been offered to him ten years ago; one is therefore obliged to acknowledge that it is because of his eminence as a scien-

tist and his present position as President of both the Royal Society and the British Association. Still, after all, the important and encouraging point for the whole profession is that our Upper House is no longer reserved for successful merchants, lawyers, and those who "cut, hack, tear, and shoot"—as Mr. Godkin describes the military class in this month's *Century Magazine*—but that its doors, which have been gradually opening to science, literature, and art, have now finally admitted one who has been instrumental in saving more lives than Wellington and Napoleon ever destroyed.

Even if peerages were to be more frequently offered to members of the profession, I do not think there is the least likelihood that many would be accepted; so long as peers have to keep up what people are pleased to term the "certain state" which it is presumed must accompany that position. One of our journals assures us that the day of large practices is over for ever; and that there is now such a general leveling-up of the profession that even the most successful practitioner finds that "the road leads up hill all the way; yes, to the very end," and hence he is not likely to be able to accumulate the fortune necessary to pay for powdered flunkies and other similar gewgaws. Lately, too, the papers have been suggesting the creation of a cheaper class of consultants with fees somewhat smaller than the usual tariff; this class to be recruited from younger men waiting to move up to the higher grade,—in fact, analogous to an arrangement that exists at the Bar. The idea has not been at all favorably received. Then, again, the profession continues to increase in numbers so as to be out of all proportion to the wants of the public; the inevitable consequence will be keener competition and smaller professional incomes. This excessive growth of the profession is shown by a study of the Medical Directory for 1897. From this we gather that the profession includes 958 names more than the year before, a larger increase than has ever before occurred in any previous year, except 1894. This increase is ubiquitous, but it is interesting to note the proportion of medical men to the population in different parts of the kingdom. Thus we see that London has twice as many practitioners (two in 850) as the provinces, while Edinburgh has one practitioner to 500 inhabitants, and Dublin comes next with one to 600. It has been suggested that the disproportionate increase in the number of

medical men in these University towns is due to the fact that they attract many who earn their living by the teaching rather than by the practice of the profession. But I would also point out that very large numbers of medical men recently qualified, or traveling, or retired, give their address in one or other of the capitals of the three United Kingdoms, and that therefore the actual percentage of medical men is not as excessive in our large towns as these figures would lead us to suppose.

Amongst other causes which thin our receipts is the ever-increasing army of quacks. One rogue, a "cancer cure," has just been sent to prison; but this was not because he defrauded poor people by pretending to cure cancer, but because he made some statements which landed him on a charge of perjury. This worthy claimed to have studied and obtained his diploma in the Eclectic College of Philadelphia (a now suppressed diploma-mill, I understand) at a date when he was living in England as an artisan! But of course one conviction on a side issue will have little effect on the hordes of charlatans, and it is hardly to be wondered at that the struggling practitioner is clamoring for the Defence Societies to be active in obtaining some protection in this quarter.

Another question which is "in the air" is that of hospital abuse. That powerful body, the Charity Organization Society, appears to be intent on carrying through its scheme for a Central Hospital Board for London. This would certainly be a first real step in the direction; for this Board would contain representatives from all the hospitals and medical colleges; it would, while leaving each hospital its individual autonomy, to some extent supervise and report on how it was conducted; it would check and direct the distribution of charity; and, in brief, would regulate and federate hospital administration in London. One of the tasks it would set itself would be the reform of the out-patient department.

The action brought by a nurse against Dr. Cullingworth for wrongful removal of an ovary was, as I have already written, lost by her. The case has just come on before a court of appeal, and the verdict in favor of Dr. Cullingworth has been confirmed.

There has been a good deal of fluttering lately in the dove-cotes of the nurses. About a year ago the editor of *The Practitioner* started the exposure, not of the properly trained nurse, as he has been wrongfully accused of doing, but of the wrongly trained

or wrongly behaved nurse. His views were confirmed by many of the leading medical papers on your side, and it is quite evident that both the profession and the public in America are feeling the incubus of the "Nurse à la Mode" as much as we have. The above is the title given by a lady (not a nurse) to an article in the *Nineteenth Century*. Being in a lay magazine it will further arouse attention to certain members of the nursing sisterhood who would have brought their colleagues into considerable disfavor if this exposure had not taken place in good time.

A body of registered nurses are now in arms against the proposal to admit to their association asylum attendants, who may be excellent watchers of the insane, but have never had a hospital training in the usual sense of the term. The question is not settled yet. A large number of the nurses appear to object to the asylum attendants being enrolled in their ranks, although their own executive seems to favor the idea.

For many years past the medical papers have carried on a crusade against the antique, ridiculous, and disgusting manner in which the oath is administered in our courts of justice. In case it should be unknown in the States I may briefly state what takes place: The witness has an old, filthy New Testament thrust into his hand; an official of the court gabbles over the form of an oath into his ear; and then tells him hurriedly to "kiss the book." This he does in a thoughtless manner, at the same time placing his lips either to the frowsy cover or on one of the soiled pages. Now, it has been discovered that a witness may, if he prefers it, be sworn in the Scottish manner, *i.e.*, with uplifted hand and repeating after the judge the form of oath. Needless to say that this form is free from all sanitary objections which may be urged against "kissing the book," while it is infinitely more dignified and solemn. The medical profession have been the pioneers in introducing, or rather I should say of reviving, the swearing with uplifted hand; and the presiding judges have not infrequently taken advantage of their position to throw cheap ridicule on what they termed the latest sanitary fad of the doctors. Now, at last, the luminaries of the law are themselves realizing the advantages of the Scottish form of oath, and it is proposed that the more usual, but objectionable, method should be abolished.

Are tropical climates particularly inimical to Europeans? The subject is considered in

a well-reasoned, and, as the French would say, "*très documenté*" article in the *British Medical Journal* by Dr. Luigi Sambon of Rome. I dare say some of your readers will remember his courtesy and kindness to visitors to the "Eternal City" during the last International Congress. The subject is of particular interest to a colonizing nation, such as we are, and Dr. Sambon's conclusions are very suggestive. They are, in brief, that if Europeans would but study their new surroundings, and try to adapt their customs accordingly, there is no reason why they and their children should not thrive as well as, if not better than, the natives. Heat, as such, he holds to be rarely the cause of death or disease, for the human body can endure high temperature with impunity. Even "heat stroke," according to his views, is probably not the result of high temperature, but of some germ which becomes active under certain circumstances, of which the high temperature is one. Considering how the average Britisher scorns to alter his insular habits in any way whatever it is really remarkable how he not only survives, but even thrives, in the climates and in the circumstances where he has made himself quite at home. For instance, "India Pale Ale" is an alcoholic beverage which drinkers of light German beer would consider extremely heavy, and yet, as its name indicates, it is the concoction especially brewed for consumption in a tropical climate. To-day I saw a returned colonist from Buluwayo, and he informed me—as if it had been his chief grievance—that whiskey there cost \$20 a bottle. He would doubtless have looked upon me as a scientific crank if I had suggested that whiskey was not at any price the drink for South Africa. The subject raised by Dr. Sambon is an interesting one, and might, if public and governmental attention was directed to it, be a most valuable one. The study of it might prove a very feasible one in the States with their great variety of climate.

The Roentgen rays have temporarily given place in professional interest to the bubonic plague. The history of previous outbreaks in England, including that of the "Great Plague," has been studied under the fresh light of modern knowledge, and many of our journals have published articles by those of our community who have formerly practiced in the East.

In the summary of last year's medical work the most serious blot is, according to my way of thinking, the number of deaths from anes-

law unhappily did not have as much success as was expected of it.

In 1874, however, Dr. Roussel introduced a law which bears his name and which establishes an inspection of all children placed out to nurse. Such a law was undoubtedly needed in a country such as France, where the custom was so general in all large cities of sending the children of the lower classes away into the country to be brought up by hand; the children of the upper classes were nursed at home, it is true, but by hired wet-nurses, who, in turn, had to give their own children to be brought up by hand elsewhere.

A month or two ago Dr. Edward Toulouse, chef de clinique of Mental Diseases, and physician of the Sainte Anne Insane Asylum, published a work entitled "Enquête Médico-psychologique sur les Rapports de la Supériorité Intellectuelle avec la Néuropathie; tome I, Emile Zola" ("A Medico-psychological Examination of the Relations Existing between Mental Superiority and a Neuropathic Condition; Volume I, Emile Zola"). In this work Dr. Toulouse gave the results of experiments which he had performed or caused to be performed on Zola, such as his sensitiveness to pressure, his power of vision, etc. In addition, the pathological history of Zola's family and of the subject himself was described. We learn, for instance, that Zola's mother was subject to certain nervous attacks, and that in his youth Zola himself was affected by a spasm of the orbicularis muscle of the right eye. We learn, too, that Zola is the subject of polyuria; that though he is fifty-six years old his arteries show no symptoms of atheroma; that though formerly a great eater, he is the opposite at present, owing to a tendency to stoutness. His visual field is normal, his tactile power above the normal, but his olfactive power below it. A number of mental tests were likewise employed.

Dr. Toulouse comes to the conclusion that Zola is neither epileptic, hysterical or insane, notwithstanding the existence of various nervous affections, contraction of the orbicularis muscle, cardiac attacks, pseudo-angina pectoris, sensory disturbances, impulsive and oppressive ideas. Zola might strictly be classed among superior degenerates.

Among others who have been examined by Dr. Toulouse are such well known men as Alphonse Daudet, Puvis de Chavannes, Saint Saëns, Berthelot, Jules Lemaitre, and the late Edmond de Goncourt.

As Dr. Toulouse's book is intended to be an attack on the theory of Lombroso that

genius is a species of epileptoid psychosis, this latter author has written a reply which is published in the *Semaine Médicale* of Paris, January 6, 1897, in which he claims that the very facts given by Toulouse in his work are an argument in favor of Lombroso's theories.

In the first place Lombroso has insisted on the advantages of crossing of races and of change of climate. Now Zola's father was an Italian, his mother French; the paternal grandfather was a Dalmatian, and the paternal grandmother Greek.

Lombroso has called attention to the advanced age of the fathers of many illustrious men, such as Napoleon I, Frederic II, Balzac, Burns and many others. Zola's father was married at forty-three years and died eight years later.

Zola's mother, too, according to what Dr. Toulouse himself writes, suffered from nervous attacks of a hystero-epileptic nature, beginning with the globus hystericus, going on to tonic convulsions with contracture, followed by more extended convulsions with subsequent partial amnesia, or even at times sensorial attacks, which were perhaps hallucinatory in nature.

Lombroso ends by affirming that any one bearing in mind the morbid ideas of Zola, his nocturnal fears, his gastric disturbances and mental anguish under certain circumstances, his attacks of vertigo after intellectual work, the contracture of the orbicularis muscle, the polioencephalitis from which he suffered in youth, and his heredity, could doubt no longer that all of Zola's work corresponds to a hystero-epileptic psychosis.

Dr. Henry Duchesne, of Sainte Anne d'Auray, has recently treated thirty-one cases of enteric fever in the following manner, with but two deaths, one being that of a confirmed drunkard:

1. The patient to drink as much as he may desire to of slightly acidulated drinks, water barely reddened with wine, etc.

2. A daily lukewarm enema, to which twenty centigrammes of a 2½-per-cent. solution of carbolic acid is added.

3. Sixty centigrammes of quinine sulphate administered daily in two doses.

For diet, milk only; no beef-tea, or soup of any kind; no astringents, Spanish or Quinquina wines, or bitter macerations; and, above all, no bismuth.

This Dr. Duchesne considers to be the best treatment for the country, where it is impossible to apply cold baths, from the lack of the necessary apparatus and assistants.

### NOTE ON THE LOCAL ACTION OF TETANUS TOXIN: WITH A SUGGESTION AS TO ITS THERAPEUTIC EMPLOYMENT.

By R. L. PITFIELD, M.D.,  
Philadelphia.

In experimental tetanus induced in animals either by inoculation with tetanus pus, cultures, or toxin, it is well known that the parts nearest the site of inoculation become affected first. It is generally thought that the action of the toxin is upon the cord; the higher cerebral centres are never directly affected,

No post-mortem lesion has been discoverable in the cord in tetanus until recently, when, in common with other poisons, Marenesco (*Compt. Rend. Biologie*, July 4, 1896) describes softening of the gray matter found in animals killed by tetanus.

The action of the poison has been compared to that of strychnine; like it, it is no doubt a direct irritant to the cord. There is also marked local action, at least in experimental tetanus.

To study this, four healthy guinea-pigs were each inoculated in a different leg, two with pus and two with toxin. In each animal spasms began in the injected limb, creeping to its opposite fellow and finally killing

the animal in general convulsions. The injection of the poison is painful, much more so than the injection of diphtheria toxin; it seems to be a direct irritant to the sensory as well as motor filaments of the nerves.

Clinically the typical attack of tetanus begins in the muscles of the jaws and face, even if the lesion be remote—say in the foot. In the case related by Welch in Dennis' "System of Surgery," vol. i, a bacteriologist named Nicolar, having accidentally pricked his left hand with a hypodermic needle moistened with tetanus toxin, was seized with a violent attack of tetanus; the contractures began after three and a half days in the left thumb, spreading to the hand and arm. Trismus, opisthotonos, general contractures and convulsions followed, and at the end of forty-one days the patient recovered. It will be seen that trismus did not occur until after local contractures had spread up the arm, showing that the action was first local, acting upon the nerve-endings, finally upon the higher cord, and thence descending.

Not knowing of Nicolar's experience, I injected one cubic centimeter of a much less virulent toxin into the calf of my left leg. The toxin was virulent to a degree, however; the same dose four days previously had killed a 455-gramme guinea-pig in forty-eight hours. The injection was more irritating than an ordinary hypodermic injection, and the parts became rapidly more and more painful. An hour afterwards my leg hurt considerably, there was no increase in any reflexes, and my temperature had risen one degree above normal. I had a headache and felt giddy. Two hours after injection the temperature fell to normal, but the pain became intense; there was spasm of the fibres of the muscles, which became greatly aggravated with use. The only manifestation of the poison was local, but it was most severe and lasted twelve hours.

It has been suggested that the filtrate of tetanus cultures is really not a poison but a creator of toxic substances in the body, by reason of a supposed enzymic action.

It may be that trismus and general manifestations of tetanus are reflexes depending upon an irritation of the terminal filaments of sensory nerves, while the local action is upon the motor-nerve terminations. No pain other than inflammatory is noticed in an infecting wound in clinical tetanus.

Toxin can be recovered from the urine in cases of tetanus, showing that it circulates freely. Most of the toxin remains in the

tissues near the wound; sufficient to kill escapes, however, since excision of an infecting wound one hour after it is made will not save the animal (Kitasato).

If the action of large doses is sufficient to cause softening of the cord, the toxin in small amounts might have a specific stimulating effect upon the cells of a cord undergoing degenerative changes, especially with atrophic manifestations in the muscles. With this in view, at intervals of a few days I administered small but increasing doses of a mildly virulent toxin to a man with mixed sclerosis of the cord. The first dose, .02 cubic centimeter, was followed by a slight rise of temperature. This was true of the second, third, and fourth doses; the latter, two cubic centimeters, caused no local reaction, but a marked exaggeration of already abnormally increased reflexes. Ankle clonus, previously hard to elicit, was easily produced, with strong contractions. Unfortunately, while I was developing some stronger toxin, the patient left the hospital feeling better and claiming to have been benefited.

Such treatment might be of use in subacute or chronic myelitis, especially in children. In case of accident the antitoxin can be used. The patients, of course, would gradually become immune to the poison.

---

#### *THE HISTORY AND TREATMENT OF AN INTERESTING CASE OF OVARIAN AND UTERINE NEOPLASMS.*

---

BY ALFRED G. DALE, M.S., M.D.,  
Attending Surgeon Iola Hospital, Iola, Wisconsin.

---

This paper is the outgrowth of many requests from different practitioners who have indirectly heard of the case in question and desire a more accurate account of what one called a "pathological museum."

It is not entirely the pathology in this case that excites the interest, but the size and disposition of the morbid growths are responsible as much as any other factor for the demand for the history and subsequent radical measures instituted for their relief. The case represents one of those exaggerated pathological conditions seen by our surgeons, manifesting the most advanced types of benign neoplastic life.

The patient, a German lady, forty-six years of age, was admitted to the hospital eight months ago, and gave the following history: She had never had any children, and prior to four years ago always considered herself a ro-

bust, healthy specimen of her race. During the enjoyment of absolute health she was suddenly taken, about four years ago, with menorrhagia, which continued with intermissions and exacerbations over a period of twelve months, at the expiration of which time she was so completely exhausted, so nearly exsanguinated, that she was compelled to keep the recumbent position for two or three months, an abject, bedridden invalid. When she finally regained strength and again assumed charge of her household duties, she began to experience moderate pain at the site of the uterus, and discovered a tumor in that locality. Not long thereafter her family physician discovered a second tumor on the right side, then shortly a third on the left side. He recommended a radical operation at the time, but the patient postponed radical measures and followed simply expectant treatment. The growths gradually increased in size, attended by a corresponding increase and exaggeration of all concomitant symptoms incident to the development of intra-abdominal tumors; especially prominent among these were dyspnea and severe pressure-symptoms with extreme vesical irritation and tenesmus, edema of the lower limbs, varicose enlargements of the legs, hemorrhoidal veins, and disorders of digestion.

When the patient entered the hospital the growths had reached enormous proportions, the abdomen was exceedingly distended and severely tense and resisting even to the ensiform cartilage. The recumbent position was no longer possible, and the patient suffered from frequent recurring attacks of syncope and painful traction symptoms due to adhesions.

Prior to the operation her bowels were unloaded completely by large doses of compound licorice powder and warm enemata; the whole body was subjected to two thorough hot baths followed by brisk friction; the vagina was sterilized, and all necessary external antiseptic precautions instituted incident to a laparotomy. Upon opening the peritoneal cavity an enormous pedunculated unilocular ovarian cyst was confronted, springing from the right ovary; it occupied the whole available abdominal space, extending from the diaphragm to the floor of the pelvis. After drawing off the cystic fluid, it was necessary to enlarge the abdominal opening to ten inches in length in order to bring the sac through the incision; and after loosening some adhesions between it and a few loops of the small intestines, right oophorectomy then

removed its attachment. In examining the left ovary it was found to be sclerotic and to give rise to four well defined and separate multilocular cysts ranging in size from that of a hen's egg to that of a hickory nut. Two of them were simple, one was a proliferating cyst, and the fourth exhibited very active pathological changes with glandular masses, representing a true cysto-adenoma. Here, as on the right side, the deep excision of the ovary sufficed for their removal. An examination of the uterus showed this organ also invaded by a neoplasm about the size of a large fetal head. It was deemed advisable to stop at nothing short of a complete supravaginal hysterectomy. Firm adhesions existed between the uterus and bladder; these were carefully separated. The work was much facilitated by elevating the pelvis as in Trendelenburg's position. After the tumor and uterus were disengaged and delivered, the broad ligaments were treated as lateral pedicles and tied off with double silk ligatures in mass successively, and severed between the rows. Having carried the double ligation and separation down to where a narrow mass of uterine tissue remained, which consisted only of the cervical portion of the uterus, the pedicle was constricted by a strong elastic cord of six millimeters in diameter. The whole uterus with its tumor was then cut away at a safe distance from the constrictor, and the abdominal cavity flushed out with a normal salt solution (6:1000), 110° F. After touching the pedicle with a pledget of cotton, soaked in a saturated solution of chloride of zinc, the anterior and posterior surfaces were approximated by a row of deep interrupted silk sutures, followed by a row of superficial uninterrupted silk sutures, and the constrictor removed. One end of a large iodoform gauze tampon was placed against the uterine stump and the other end brought out of the lower angle of the wound. The abdominal wound was sutured in the usual manner, over which was placed an abundant sterilized absorbent dressing.

Under closer inspection, verified by a microscopical examination, the uterine tumor was found to be an intra-mural fibromyomata. The tenacious mucoid fluid drawn off from the large cyst was preserved, and measured 18.08 litres (four gallons). The uterine fibroma, the four smaller ovarian cysts, the fluid and sac of the large cyst, were all weighed, and aggregated fifty-six pounds.

The patient evinced severe symptoms of

shock for the first twenty-four hours. Artificial heat was supplied by the judicious use of hot-water bottles and the internal medication every fifteen minutes of two grammes of brandy, and 0.6 gramme of tincture digitalis and 0.002 gramme of sulphate strychnine were administered hypodermically every alternate hour until reaction was well established.

The gauze tampon drainage was removed on the fourth day and the abdominal wound redressed. The patient left the hospital in five weeks, and when last heard of she reported an absolute uneventful recovery.

#### *ANTISEPTIC DRESSING OF THE GENITAL TRACT AFTER OPERATIVE DELIVERY.*

BY EDWARD P. DAVIS, A.M., M.D.,

Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Clinical Professor of Obstetrics in the Jefferson Medical College, and Medical Director of the Jefferson Maternity; Visiting Obstetrician to the Philadelphia Hospital, etc.

Artificial or operative delivery is accomplished without injury to the patient by following the same rules which govern active interference in surgical procedures. In many labors the seat of operation, the genital tract, is in an aseptic condition when interference is undertaken; the hands and instruments of the obstetrician are sterilized, as are those of the surgeon, and it remains for the former to leave the tissue operated upon protected by a suitable antiseptic dressing.

After most instrumental deliveries, wounded tissue is found in three portions of the genital tract: The pelvic floor and perineum are often lacerated, and such tears require dressing, although they may be slight in extent; the cervix uteri is frequently more or less lacerated, and such wounds may readily become infected; the site of the placental attachment within the uterus may also readily absorb septic poison. It is the duty of the obstetrician after labor to leave, if possible, the entire genital tract of the patient in an aseptic condition, and protected from the invasion of septic poison; in other words, wounds in the genital tract should be closed and antiseptically dressed just as much as those in the abdominal cavity, or in other regions of the body.

After normal labor in a healthy woman, the wounds already enumerated are but slight in the cervix and pelvic floor; they are cleansed by the amniotic liquid and blood-serum of the lochia, and unless the parts are

infected at labor, they are after labor in an aseptic condition. If an occlusion antiseptic dressing be placed over the vulva of such a patient, if this dressing be renewed as often as indicated, and the external parts thoroughly cleansed, no direct application is needed for the minor tears after normal labors. When, however, considerable lacerations are present, and especially in young, ill-developed, anemic women whose poor condition favors infection, an antiseptic dressing is urgently required. In choosing such material, it must be capable of exerting gentle pressure, and also of furnishing capillary drainage; antiseptic gauze fulfils this purpose in obstetric practice quite as well as after vaginal hysterectomy.

While some have cast doubts upon the virtues of iodoform as an antiseptic, still the majority of operators are content to use this material within the abdomen or in the uterus. Others prefer, for intra-uterine packing, bichloride gauze 1:2000; either of these materials is now put up by manufacturers in small glass bottles, hermetically sealed, containing sufficient to tampon the uterus and vagina after labor. Such a bottle should not be opened until its contents are required, when the gauze can be taken directly from the bottle and inserted in the body of the patient.

The immediate result of the presence of the gauze within the uterus is to stimulate uterine contractions, and to prevent the formation of a clot of considerable size. The lochial discharge is serous only, but little hemorrhage occurring. In cases thoroughly cared for under antiseptic precautions, the lochia is always serous and endures for a shorter time than in cases not treated in this way.

The reader must distinctly understand that the use of gauze dressings within the uterus and vagina after labor is not proposed after normal labor; it is, however, practiced and commended after cases where birth occurs by operative interference, or where uterine relaxation and hemorrhage are threatened.

In conducting operative cases the physician must prepare to deal with laceration of the genital tract. While the patient is being anesthetized the operator should prepare his forceps, needles, needle-holder, hemostatic forceps, scissors, and suture material, and a pair of curved uterine dressing-forceps for introducing the gauze. While several instruments have been invented for this purpose, they are not superior to a pair of slender

dressing-forceps, which should be perfectly smooth at the ends which grasp the gauze; the serrations usually found on such forceps are very inconvenient, as they tend to pull back the gauze when the operator has introduced it.

The patient being anesthetized, the delivery is accomplished by either version or forceps, or by embryotomy. The patient may then be allowed to come partly from the influence of the anesthetic, when the placenta is expressed with the aid of the patient; or, if haste is imperative, the placenta is removed by Cr  d  's method without allowing the patient to regain consciousness. The uterus is thoroughly explored with the aseptic hand to be sure that all portions of placenta and membranes have been removed; it is then thoroughly douched with bichloride solution 1:8000, or creolin two per cent., at a temperature of 110   F. While the hand of an assistant or nurse rests upon the uterus above the pubes, the operator introduces several fingers of the left hand within the vagina and below the cervix to act as a guide; the end of the gauze is then taken by the dressing-forceps, and gently carried to the fundus of the uterus; the womb is moderately filled with gauze, the end of which is left protruding from the internal os. The hand of the operator is then removed, and the lips of the cervix are grasped in the centre by hemostatic or tenaculum forceps, and the cervix drawn gently downward until a thorough examination can be made of each lip. If lacerations are present, they are closed with chromicized catgut, or with soft silk of large size. The uterus is then anteverted, and the pelvic floor, if lacerated, is repaired; also the perineum, if needed. When lacerations have been closed, the vagina may again be douched with bichloride 1:8000, the cervix carried backward, the fundus being placed forward against the pubes, and the vagina moderately distended with bichloride gauze. If shock or relaxation of the uterus be present, strychnine is given, one-fifteenth to one-twentieth of a grain, hypodermically; the external parts are thoroughly cleansed with bichloride solution; the patient may be catheterized to advantage, and an occlusion bichloride dressing be placed over the vulva and retained by a T-bandage, or fastened to the lower edge of the abdominal binder. The gauze dressing is left in place thirty-six to forty-eight hours, the patient being catheterized meanwhile at regular intervals, and strict care taken that the external parts are

thoroughly cleansed with bichloride solution 1:2000 before and after the emptying of the bladder or of the bowel.

To remove the gauze, the patient should be placed upon her back across a bed, her feet on chairs, while the operator inserts one or two fingers of the aseptic hand, passing them along the anterior vaginal wall to avoid contact with stitches in the pelvic floor. The gauze is gently extracted with dressing-forceps, and the uterus thoroughly douched with bichloride solution 1:8000, or creolin. A copious douche should be given, until the water returns perfectly clear. After the removal of the gauze, and the douche, an external occlusion dressing only is needed, and the case becomes one of the ordinary puerperal state. Such patients, however, are rarely annoyed by the formation of clots within the uterus, while the lochia continues serous and ceases sooner than in cases in which the gauze is not employed. Should a rise of temperature above 100   occur, the uterus should be again thoroughly douched, when the temperature will usually rapidly fall.

The writer's case-books show abundant evidence of the practical value of this method of treatment. It is rare for these patients to have any complication, while complicated deliveries make a more speedy and uninterrupted recovery. He has never had occasion to introduce gauze a second time in the same patient, and has often removed the gauze as early as thirty-six hours after delivery, without complication. In cases where previous infection was present, in the form of syphilis or gonorrhea, such patients have been unusually free from offensive lochia during the puerperal period.

The following cases may indicate those in which this method of treatment may be used to advantage:

CASE I.—Primipara; normal pelvis; delayed labor through resistance of the cervix. Dilatation by McLean's bag, followed by partial engagement; ether anesthesia; Walcher's position and extraction with forceps; cervix and pelvic floor closed by suture; gauze packing of uterus and vagina. On removing the gauze forty-eight hours after its insertion, a small piece of placental tissue was found adhering thereto. Patient made an uninterrupted recovery from labor.

CASE II.—Multipara; death of fetus at seven months from anemia of the mother; spontaneous labor; adherent placenta. Chloroform anesthesia; the uterus curetted with

the blunt douche-curette, and packed with iodoform gauze; the vagina tamponed with sterile gauze. Uninterrupted recovery of the mother, her highest puerperal temperature being 99½°.

CASE III.—Young anemic primipara; prolonged labor; rupture of the membranes; episiotomy; delivery by forceps; gauze packing of uterus and vagina. The patient made an uninterrupted puerperal recovery.

CASE IV.—Multipara; very anemic; formerly resided in Cuba; suffered for several weeks from obstinate pain in the left sacro-iliac joint; normal pelvis. Labor induced on account of mother's weak condition. Cervix excessively thick, requiring dilatation with McLean's bag; forceps delivery; removal of adherent placenta; laceration of one side of cervix, sutured with catgut; gauze packing of uterus and vagina. Patient recovered well from puerperal period, and transferred to orthopedic ward for treatment of the pelvic joint.

CASE V.—Primipara; weak and anemic; prolonged labor from uterine inertia. Slow rotation of the occiput; dilatation by McLean's bag; forceps delivery; tamponing of uterus and vagina with gauze. Highest puerperal temperature 100°. Uninterrupted puerperal recovery.

CASE VI.—Primipara, aged forty; prolonged labor from uterine inertia at term; pelvis normal. Extraction with forceps under ether; tamponing of uterus and vagina with gauze; slight laceration of cervix and pelvic floor, closed by suture. Uninterrupted recovery.

CASE VII.—Multipara, brought by ambulance from a tenement house where she had been in labor several days; child in transverse position, arm prolapsed, and beginning gangrene of the arm; uterus in tetanic contraction, threatened rupture; patient greatly exhausted; fetus wedged in the pelvis, so that version was impossible. Embryotomy; amputation of the arm at the shoulder, breaking up the wedge and permitting version; delivery accompanied by severe hemorrhage; tamponing of uterus and vagina with gauze. Following the removal of the gauze, the patient had a single rise of temperature from sapremia, which yielded promptly to a copious irrigation of the uterus; subsequent recovery uncomplicated.

CASE VIII.—Multipara, brought in by ambulance during an abortion; hemorrhage and slow dilatation; fetal limb presenting. Dilatation completed with Barnes' bag; fetus and

appendages removed with finger, and uterus douched with curette; packing of uterus and vagina with gauze. Beyond a brief rise of temperature from sapremia, patient's recovery uncomplicated.

CASE IX.—Young primipara; normal pelvis; suffering from polyhydramnios, with rapid increase in the amniotic fluid; general anasarca present, and abdominal pressure so great as to prevent sleep and cause great suffering; uterine distention excessive; os dilated, but uterine contractions absent. Rupture of the membranes, followed by slow delivery, with careful and prolonged counter-pressure upon the abdomen; excessive discharge of amniotic liquid, with feeble uterine contractions; after delivery, tamponing of the uterus and vagina with gauze, with the application of many-tailed abdominal bandage. Patient made an uninterrupted recovery.

CASE X.—Primipara; flat rachitic pelvis. Induced labor; symphyseotomy; extraction, with forceps, of living child; tamponing of uterus and vagina with gauze, which remained forty-eight hours. No post-partum hemorrhage, or relaxation of the uterus. Patient made a good recovery.

CASE XI.—Primipara; justo-minor pelvis of slight contraction; rupture of perineum in median line; suture; tamponing of uterus and vagina with gauze. Uninterrupted puerperal recovery.

CASE XII.—Multipara, who had lost her first child by birth-pressure from forceps extraction. Induction of labor at thirty-fourth week to avoid excessive size of fetus; artificial dilatation with McLean's bag; extraction with forceps; manual removal of the placenta; gauze packing of uterus and vagina; gauze removed in thirty-six hours. Uninterrupted puerperal recovery; child, a male, weighing nine pounds; diameter of head from one to two centimeters in excess of the average.

CASE XIII.—Multipara; seen in consultation with Dr. Thomas Betts and Dr. E. L. Klopp, of Oak Lane, Philadelphia; flattened pelvis; first child died of birth-pressure following forceps extraction; patient without a trained nurse, and with limited appliances for aseptic precautions; two attempts had been made to deliver with forceps. Anesthesia with ether; patient placed upon a table in Walcher's position; extraction of living child with axis-traction forceps; removal of the placenta; thorough douching of the uterus; closure of cervix and of slight tear in pelvic floor with silk; uterus packed with iodoform

gauze, and vagina with bichloride gauze. Dr. Betts removed the gauze forty-eight hours afterward, finding a few small, soft clots adherent to the gauze, and a serous discharge only; patient's highest temperature 100°; mother and child made good recovery.

While many of these cases have been delivered in the Jefferson Maternity with all the advantages of good nursing and abundant assistance, still Cases XIII and XIV illustrate the advantages of this method in private houses. In Case XIII, an excellent trained nurse and the writer's personal assistant were present; the patient had every advantage which thorough asepsis and abundant private resources could give. In Case XIV, the patient's limited means deprived her of many advantages in her own home, and her husband would not permit her to go to a hospital. It is in such cases, especially where it is difficult to maintain a thoroughly aseptic condition of the patient after delivery, that the employment of this procedure will be found especially advantageous. It is true that to be theoretically accurate, all samples of gauze should be tested by bacteriological examination before the operator introduces them within the uterus; this, however, is not practicable in most cases, and good results are obtained with the employment of strict cleanliness, thorough douching with dilute antiseptic solutions, and care that the gauze is conveyed directly from its case to the uterus of the patient, and is not opened or touched before its introduction. We have yet to observe any complication which we have been able to trace to this procedure.

---

**ECTOPIC GESTATION: A REPORT OF OPERATIVE CASES; WHEN TO OPERATE; POINTS IN TECHNIQUE.**

---

By J. COPLIN STINSON, M.D.,  
San Francisco, Cal.

---

During the past few years much has been written on this subject. A review of the several methods of treatment shows that the mortality is lowest in those cases in which early operation is employed. In deciding on an operation for ectopic gestation the question arises, When and how shall we operate? I am of the opinion that if the diagnosis is made before rupture has occurred, operation should be made through abdominal incision as soon as arrangements can be made. With careful antiseptic and aseptic precautions, provided the operator is familiar with the

special anatomical conditions associated, an abdominal operation has in itself a mortality at or about *nil*.

We can never tell when rupture is going to take place; it may occur after our visit, perhaps not for a week, or after the lapse of months. We can guess as to the probable time of rupture, and that is the best we can do.

If we are called in after rupture has occurred, what is the best plan to follow? I would say operate as soon as possible. If the patient is collapsed, do not waste time waiting for reaction, for frequently, the hemorrhage continuing, reaction does not occur, and the patient is lost. When rupture occurs there should be no delay. The patient should not be removed from the house, but preparations should be made at once, and the operation performed under antiseptic and aseptic precautions as quickly as it can be done with accuracy. While the preparations are being made, if the patient's pulse is failing, hypodermics of digitalis, camphor, strychnine, etc., and intravenous or subcutaneous injections of sterilized salt solution at about 105° F., should be administered. We can only save the patient by arresting the hemorrhage, and the quickest and safest way is to cut down, clamp and tie the bleeding vessel. If the patient is under the care of a medical man no time should be wasted, but a surgeon should be called in to operate at once, so as to give the patient every chance for her life. We may use palliative, plastic and conservative methods in most conditions of the appendages, but we must be prompt, radical, and scientific in our operations for ectopic gestation.

In looking over my list of ectopic cases in which I performed or assisted in an operation while house surgeon at the New York Post-Graduate Medical School and Hospital, and since I left that institution, I find they number six. There was one other case not operated upon, the history of which I shall also include in my paper. Of these cases one was unruptured, six ruptured.

CASE I.—Unruptured; period of gestation, between two and three months. A three-inch median incision was made above the pubes, and the peritoneum was opened; the ovary and tubal mass were brought to the surface and removed; the pedicle was transfixed and tied off; abdomen was closed in separate layers with catgut sutures; silkworm-gut for the skin; no drainage. Recovery satisfactory.

**CASE II.**—Ruptured; near the third month of gestation. About three weeks previous to the operation there was a slight hemorrhage. Examination showed a moderately adherent mass, size of an orange, on one side of the uterus. A median incision four inches long was made above the pubes; on opening the peritoneum the mass was found moderately adherent in the pelvis; the adhesions were separated, ovary and tubal mass removed, pedicle transfixed and ligated, and abdomen closed without drainage. The tubal mass showed signs of the recent rupture. The peritoneum and fascia were sutured separately with catgut; interrupted silkworm-gut sutures were also used through all the structures of the abdominal wall except the peritoneum. Convalescence was delayed by an abscess which formed in the line of one of the worm-gut sutures; the abscess was incised. Otherwise recovery was satisfactory.

**CASE III.**—Period of gestation, between the second and third months; the rupture occurred on a Sunday morning. The patient was operated upon the afternoon of the same day. The abdomen was opened in the median line above the pubes by a four-inch incision; on opening the peritoneum the cavity was found to contain some large clots; the clots, ruptured tube and ovary were removed; the pedicle was transfixed and tied off; the abdomen flushed out with hot water; the peritoneum was closed with catgut, and the other layers were approximated by a single layer of interrupted worm-gut sutures. No drainage was used. There was some shock after the operation, but reaction was good. Wound healed by primary union; recovery uneventful.

**CASE IV.**—Period of gestation, about the third month; the rupture had occurred two days previous to entrance to the hospital. When admitted the patient was in a critical condition; pulse 135, temperature 102°; abdomen tympanic and markedly tender, especially the lower part, which was occupied by an ill-defined tumor mass; cervix enlarged and patulous; some bloody discharge; uterus enlarged about size of the second month of pregnancy. The mass could not be clearly defined by bimanual examination, but was traced downward into the pelvis. In one cornua of the uterus was an irregularly shaped mass, the size of a large orange. Operation was performed under ether. On opening the abdomen, the ill-defined mass was found to consist of large, partly organized blood-clots. The cavity also contained some blood-stained

serous fluid; there was evidence of peritonitis in the pelvis. The clots and serum were removed, adhesions separated, and the uterus and the mass in one uterine cornu were outlined; the ruptured ectopic mass was located at the tubo-uterine junction; the cornu was dilated, torn, and occupied by a portion of the mass about the size of an orange. The adhesions were separated, and the mass, including the ovary, was tied off close to the uterus and removed. The other tube was found enlarged and distended with fluid, and was also removed. The adhesions behind the uterus were separated and an incision made through the cul-de-sac into the vagina; abdomen was flushed out with hot water; iodoform gauze packing introduced into the pelvis from above, and the ends drawn down into the vagina. The abdominal incision was sutured in separate layers with catgut, using also interrupted worm-gut through all the layers of the abdominal wall except the peritoneum; no drainage was employed through abdominal wound; aristol dusted on wound and dressing applied. When patient was returned to bed, condition was poor; pulse 160. She was given stimulating enemata at two-hour intervals, and hypodermics of strychnine,  $\frac{1}{16}$  grain, and whiskey every hour for several doses. After vomiting ceased the patient was given one-half a Seidlitz powder in hot water every half-hour till four powders were taken. The vaginal drainage was good for several hours; the gauze was drawn down about every two hours; drainage was slight eight hours after the operation. Introduction of catheter into the bladder twelve hours after the operation showed but little urine. Vomiting set in; temperature gradually rose to 104°; abdomen became distended; kidneys stopped secreting; and the patient died. Temperature before death, 104½°.

Autopsy showed peritonitis and acute nephritis. This patient, I think, would have had a better chance for recovery if chloroform had been the anesthetic used instead of ether, and if the abdomen had also been drained from above through the lower angle of abdominal incision by two or three moist gauze wicks.

**CASE V.**—Rupture had occurred between the third and fourth months of gestation, and the fetal mass was discharging into the rectum. Operation was performed under ether. Patient was placed in the lithotomy position and the fetal mass, in a foul condition, was extracted piecemeal; the cavity was then washed out with hot salt solution, and a

gauze wick introduced for drainage. The cavity gradually filled up, and recovery was uneventful.

**CASE VI.**—The patient had a rupture when she was about two months pregnant, and made a good recovery. When she was admitted to the hospital the pregnancy was between the third and fourth months; patient's general condition was good. Examination showed the cervix slightly enlarged and patulous; on one side of the pelvis near the cornua was a large tumor mass, slightly adherent in the pelvis. The patient was to be operated upon the following morning before the class of Post-Graduate students. At 7.30 P.M. she was shaved and antiseptically prepared; about 9 P.M. I was called to see her. I hurried to the ward and found her pale and collapsed. Examination of the abdomen showed the lower portion tender to the touch; palpation elicited a boggy feeling. The patient was given hypodermics of morphine, strychnine, and digitalis, and preparations were made for operation. She began to vomit and died in a few minutes, before operation was performed.

The autopsy showed the abdomen to be nearly full of blood; there were evidences of the old and recent ruptures; the recent one had taken place into the peritoneal cavity; the tube was markedly enlarged and moderately adherent in the pelvis, and near to and attached by the cord to the ruptured tube was a fetus of about four months.

**CASE VII.**—Ruptured ectopic gestation, local peritonitis, hydrosalpinx. The patient was admitted to the hospital in a critical condition; she had considered herself between the third and fourth months of pregnancy. A week before entrance to the hospital abortion had been attempted; this produced pain and hemorrhage; for the latter vinegar was injected, and this increased the severity of the pain, which extended from the pelvis into the lower part of the abdomen. She suffered intense pain for three days previous to admission to the hospital.

Examination: General condition poor; pulse 140; temperature 102°; abdomen tympanitic and markedly tender, especially over lower half, on the right side of which an ill-defined tumor could be mapped out; the cervix was enlarged and patulous; the mass felt through abdomen could be traced downward into the cul-de-sac; on the left side, close to the uterine cornu, was an oval mass the size of a large orange.

Operation was performed as soon as the

operating room was ready; anesthetic, ether. Patient was shaved and antiseptically prepared. A median incision four inches long was made below the umbilicus, and the peritoneum opened. The mass felt through the abdomen consisted of large clots of blood, and the cavity contained some blood-stained serous fluid. The clots and serum were removed, adhesions separated, and the oval mass to the left of the uterus outlined. This consisted of fetus and membranes, together with matted tube and ovary; these were removed, the pedicle being tied off close to the uterus. Examination of the right tube and ovary showed a hydrosalpinx the size of a sausage; this was removed along with the ovary, which was the seat of extensive cystic disease. The serous coat of the intestines, which was torn in several places while separating adhesions and removing clots, was sutured with fine silk; the adhesions behind the uterus were separated as far as possible; the abdomen was flushed out with hot saline solution; iodoform gauze strips were packed into the cul-de-sac through the abdominal incision; an iodoform gauze strip was carried down behind the uterus, and the end brought out through the lower angle of abdominal incision; the abdomen was closed in separate layers with catgut, leaving only sufficient room at the lower angle for the gauze strip; aristol was dusted on wound and the dressing applied. Patient was then placed on her side; cervix seized with vulsella and drawn down; an incision made behind the cervix into the cul-de-sac, and the ends of the iodoform gauze packing drawn down into the vagina. Patient was returned to the ward; condition poor; pulse 160. She was given stimulating enemata twice at two-hour intervals, and hypodermics of strychnine  $\frac{1}{10}$  grain, caffeine 2 grains, and camphor 3 grains, every hour for four doses. Pulse at the end of four hours became fairly good. One hour after vomiting ceased, was given one Seidlitz powder in hot water every hour till four were taken. At the end of six hours she was given an enema of olive oil 4 ounces, Rochelle salts 4 ounces, enema  $1\frac{1}{2}$  pints. Bowels moved slightly eight hours after the operation. Highest temperature, 101 $\frac{1}{2}$ °. At the end of twelve hours patient had a severe chill; temperature rapidly rose to 106°; pulse 180. Drainage had been excellent for six hours after the operation from the abdominal wound, but poor through the vagina, on account of density of pelvic adhesions. Gauze on abdomen had been changed

as often as it was saturated—*i.e.*, about every hour and a half; the gauze through the cul-de-sac was drawn down about every two hours. Drainage was slight from the sixth hour after the operation up to the time the temperature began to rise, when the dressing on abdomen was removed, and wound was opened at the lower angle for about two inches; a soft rubber catheter was passed down into pelvis and about half an ounce of blood-stained fluid was withdrawn with a syringe. Another strip of gauze was introduced to the bottom of the wound and moist dressings reapplied. The patient was given one hypodermic Majendie solution of ten minims, and an enema twice of whiskey 4 ounces, quinine 20 grains, at two-hour intervals. In four hours the temperature dropped to 103°, and inside of two days was normal. While the patient was very weak, she was given an ounce of champagne every hour by the mouth; for two days after the operation she was given nutrient enemata of peptonized milk  $\frac{1}{2}$  pint, two eggs, and salt 2 drachms, every four hours, till the stomach could tolerate milk and Vichy in small quantities. On the seventh day she was ordered regular diet. The gauze in the cul-de-sac was removed twelve hours after the operation, and the abdominal drains on the third day, when a small strip was introduced. The wound filled up rapidly; cicatrization was complete six weeks after the operation. General condition good on the last report.

*Some Points in Technique.*—The abdominal incision need not be made longer than three inches, and after opening the peritoneum, if it be found necessary to enlarge the incision on account of extensive adhesions or the size of the mass, this can easily be done. Less time is taken and less injury is done by operating through a short incision, and later on the opening can be closed in less time and with fewer manipulations. In difficult cases the Trendelenburg position should be used, as it offers many advantages. If adhesions are present separate them by blunt dissection, aided at times when they are firm by cuts with the scalpel. Adhesions, unless they are very old and firm, always give way before the normal structures. When the adhesions to the intestines are old and firm they should be cut so as to leave a piece attached to the bowel; should the intestines be torn, grasp them at once, and close the rent or rents with two layers of continuous sero-muscular fine silk sutures. Bleeding from adhesions is best arrested by irrigation with hot water

and pressure with hot gauze sponges. To prevent secondary adhesions all raw surfaces where it is possible should be whipped over by fine continuous catgut sutures. When sutures cannot be used secondary adhesion can be prevented by means of an aristol film, which acts mechanically and gives the raw surfaces an opportunity to heal separately. The aristol film will not form on the surfaces if any fluid washes away the aristol before it becomes fixed with the lymph; in from half a minute to a minute the film can be formed on a dried surface by exposure to the air. The ectopic mass should be removed by enucleation, using blunt dissection aided at times by cuts from the scalpel. The dissection should be carried as close as possible to the tubal mass; beginning the enucleation at the fimbriated extremity, work toward the uterine end of the tube. When the uterine cornu is reached, the serosa of the tube about a quarter of an inch from the tubo-uterine junction is divided in a circle and dissected back to the uterus; the tube is then cut off flush with the uterus, and the cut edges of serous coat which had been dissected back are united with a continuous catgut suture. If the ovary is irreparably damaged it is also removed by enucleation, using blunt dissection, aided at times by cuts with the scalpel; oozing is arrested by sponge-pressure. If any vessels are severed during the enucleation they are caught at once with forceps and ligated with fine catgut.

After the removal of appendage the cut edges of the broad ligament should be united with a fine continuous catgut suture. The tube and ovary of the other side should be examined, and if the ovary is cystic the latter should be evacuated, trimmed away, and the cut edges united with continuous catgut sutures. If the tube or ovary, or both, are irreparably damaged they should be removed by enucleation as described. If the uterus is in good position and not irreparably damaged, it should not be removed.

In those cases where the fetus has escaped from the tube or is not in the tube, the treatment should be the thorough removal of the fetus, placenta and membranes as soon as the diagnosis is made, no matter what the stage of the disease, removing the masses by enucleation, ligating only bleeding vessels, and arresting oozing by sponge-pressure and irrigation with hot water. If drainage is necessitated, one or more strips of moist gauze, surrounded by gutta-percha tissue with several holes snipped in the tissue

(Morris' capillary wick) answers best; the rubber tissue prevents the formation of adhesions between the serosa and the gauze. In an earlier paper on Appendicitis I reported fourteen cases in which Morris' capillary wick was used with every advantage where drainage was necessitated. In closing the wound each of the layers should be sutured separately and thus accurately with chromicized catgut or tendon sutures, using very fine silk for the skin; and if each of the divided layers is sutured separately with sterilized chromicized tendon or catgut, there would never be a post-operative hernia.

I advocate the removal of all such masses as ovarian cysts, tumors, abscesses, irreparably damaged tubes—e.g., pus-tubes, tubes the seat of gestation, etc.—by enucleation, with ligation of vessels only as I have described in my paper, as the simplest, safest and most scientific method of dealing with such masses. I have removed successfully ovarian tumors, cysts, tubo-ovarian abscesses, adherent ovaries and tubes by enucleation, ligating only the bleeding vessels with catgut. In two instances I removed an adherent ovarian cyst and tube, and an extensively adherent tubo-ovarian abscess, by enucleation without applying a ligature; no vessel was ligated or clamped, as there was no bleeding.

From a study of the cases cited, and comparison of the methods used by various physicians and surgeons, I can only draw the following conclusions:

1. That ectopic gestation is strictly a surgical disease.
2. That an ectopic mass should be removed by abdominal section as soon as the diagnosis is made, no matter what the stage of the disease.
3. That with careful antiseptic and aseptic precautions, provided the operator is familiar with the special anatomical conditions associated, an operation for ectopic gestation has a mortality at or about *nil*, or less than that associated with the condition previous to operation.
4. That an ectopic mass should be removed by enucleation, with ligation of vessels only, using absorbable ligatures; the pedicle should not be transfixed or tied off in sections, but should be cut across, and only the individual vessels ligated. This does away with mass, non-absorbable and dead ligatures, sloughing and painful stumps, pelvic exudates, the cautery, and wandering ligatures, etc.
5. That enucleation is the safest, simplest and most scientific method of removing an

ectopic mass, etc.; there is no danger of hemorrhage; if a vessel is severed, it can be caught at once and ligated.

6. That with enucleation there is less danger of injuring adjacent viscera; recovery is rapid, and the danger of sepsis is reduced to the minimum.

7. That when a Fallopian tube is removed, the operation should be complete; no stump should be left. When the serosa of the tube at the tubo-uterine junction is not totally destroyed, it should be divided in a circle about a quarter of an inch from the uterine cornua, dissected back to the uterus, and the cut edges, after cutting off the tube flush with the uterus, united by a continuous catgut suture.

8. That in removing an appendage, etc., by enucleation, the cut edges of the broad ligament should be united with a continuous absorbable suture.

9. That even when both appendages are removed, a uterus that is in good position and not irreparably diseased should not be removed.

10. That if there is local or general infection the cavity or cavities should be freely flushed with hot saline solution.

11. That if drainage is necessitated, one or more Morris' capillary gauze wicks should be used instead of iodoform or other gauze packing, glass, or other stiff tubes.

12. That to prevent hernia the incision should be small, using, if drainage is necessitated, capillary wicks, and the wound be closed layer by layer separately, and thus accurately, with sterilized chromicized tendon or chromicized catgut.

*THE TECHNIQUE OF PROFESSOR KEEN'S  
SURGICAL CLINIC IN THE JEFFERSON  
MEDICAL COLLEGE HOSPITAL.*

BY THOS. LEIDY RHOADS, M.D.,

Assistant Demonstrator of Pathology; Assistant in the Surgical Clinic, Jefferson Medical College Hospital.

While the achievement of satisfactory results in surgery does not depend alone on a refinement of operative technique which is as perfect as modern science can make it, and while it is recognized that sound judgment and thorough operative ability are most important requisites to him who expects to deal successfully with surgical maladies, yet the strict attention to detail in the care of the patient, in the cycle of his existence in the hospital, prior to, during, and after operation, must bear much weight in attaining that end which is always uppermost in the surgeon's mind—the ultimate cure of the patient. The technique which is followed in a large hospital clinic where every opportunity is offered to try the various methods advanced from time to time, to discard the faulty ones, and retain those which have stood the test of rigid and most careful examination, must be of interest to the physician engaged in surgical work, but who is not in a position to make extensive personal investigations to find out what methods are absolutely reliable.

The methods employed by Dr. Keen in the Surgical Clinic of the Jefferson Hospital, which represents one of the largest surgical clinics in the United States, are set forth in detail under the following several headings: First, the operating arena and paraphernalia at hand; second, the materials needed for each operation; third, the preparatory care of the patient; fourth, the surgeon and his assistants; fifth, the operation; sixth, the after-treatment of the patient.

The *operating arena* of the clinical amphitheatre, which is a building separate from the hospital wards, is so arranged as to be in the centre of a series of seats raised in tiers. This affords to the students on the benches a good view of the operation. Wainscoting of glazed tile, 1.5 meters in height, separates the rows of benches from the arena, which is laid with a hard, non-porous, mosaic stone floor, sloping to an air-tight drain. The floor and tile work are thoroughly scrubbed with hot water before and after each operation and mopped with a solution of bichloride of mercury 1:1000, and the floor of the amphitheatre is sprinkled with the same solution. This proceeding is made necessary by the

constant moving about of assistants and the coming and going of the large body of students. More or less dust is whirled into the atmosphere, and this repeated mopping and sprinkling is done to limit as far as possible the impregnation of the atmosphere with germs, and to prevent the wound from becoming infected from germ-laden dust coming in contact with it, the dust in the air offering the only danger. The room is lighted by an overhead skylight, a provision found necessary to obtain the greatest amount of light on the field of operation. For operations performed after sundown the necessary illumination is obtained from a drop-light of thirty-six flames suspended over the operating table, and if it is desired to have light nearer the wound, a nurse holds a portable incandescent light, which is always in readiness, in the most advantageous way and so as not to interfere with the movements of the surgeon. In brain cases at night Dr. Keen usually finds it more convenient to use an electric headlight on account of the small field of operation and to avoid crowding of assistants.

In the middle of the arena stands the operating table devised by Boldt, made of an iron frame, enameled in white, with portable plate-glass top. The simplicity of mechanism of this table is of note, as the head-rest and foot-end can be lowered, and the patient can be placed in the Trendelenburg posture at a moment's notice. On the sides of the arena are the smaller tables, two on each side, for instruments, etc., being made also of enameled iron frames and glass tops which can be lifted. These tables are scrubbed carefully with soap and water, then with a corrosive solution, and at the time of operation covered with bichloride sheets, the preparation of which will be described hereafter. At one end of the arena are two upright copper and brass boilers, of the Sprague-Schuyler pattern, each holding 115 litres, in one of which is boiling hot water and in the other water which has been boiled and cooled. The water in both has been heated to 116° C. Adjoining these is a Schimmelbusch sterilizer for boiling instruments, which apparatus has the advantage of hermetic occlusion by the cover and keeps the temperature of the boiling water equal at every point. This and the boilers are mounted on frames of the same material as the tables. Opposite the sterilizing apparatus is a large marble sink with taps of running water, hot and cold, where frequent ablutions of the hands and forearms are taken without the

use of basins, and on a glass shelf above the sink are glass jars of antiseptic solutions containing brushes, jars containing a solution of Johnston's ethereal soap—which is a solution of Castile soap in ether, and having added for coloring and germicidal properties a small percentage of pyoktanin—blunt-pointed orangewood sticks for cleansing nails, and a sterilized bowl containing alcohol. Alongside the marble sink is a large deep pan on an iron frame, all enameled, containing at the time of operation bichloride-of-mercury solution 1:1000 for disinfecting the hands and forearms. A covered metal vessel receives the soiled dressings, sponges, etc., which are removed from the room immediately after each operation. The plumbing of the sink and drain is frequently inspected and they are kept in perfect order. For the accommodation of visiting surgeons there are several chairs painted in white enamel in order to facilitate cleansing. At the other end of the arena is a small table which is covered with a sterilized sheet at the time of operation, on which are placed the necessary paraphernalia for the anesthetist's use—an Allis inhaler wrapped in a sterilized towel, an Esmarch chloroform inhaler, jaw forceps, mouth gag, tongue forceps, a bottle graduated in centimeters and containing Squibb's ether, a smaller one, also graduated, containing chloroform; hypodermic syringes ready for use, a faradic battery, and an apparatus for administering oxygen by inhalation.

Before each clinic the clinic nurse and her two assistants see that the arena is placed in order. Floor, tables, etc., are cleansed as above stated, and from the adjoining room is wheeled a rolling table on which are jars for dressings, sheets, towels, sponges, etc., which have previously been prepared in a room set apart for this purpose; the table also contains instruments on metal racks which have been taken from a glass instrument-closet in an adjoining room. These jars, etc., are placed in their regular places on the glass-top tables.

In the preparation of this material the strictest asepsis and antisepsis are observed, and the transaction is entrusted only to a nurse who has received sufficient training in this special work and who understands every detail in the preparation, which includes iodoform gauze, gauze pads, dressings and sponges, ligatures and sutures, towels and sheets, gowns, brushes, drainage tubes, rubber protective and receptacles for the various solutions. All the pads, dressings, sponges,

drainage tubes, etc., are kept in glass jars covered with glass lids, which are made sterile by scrubbing with ethereal soap and water, scalding and filling them to the brim with mercuric chloride solution 1:1000, and allowing them to stand thus over night. In the morning this solution is poured off and the jars are ready for use. This sterilization is repeated each time the jar is emptied of its contents, which may be in a day or at the end of several days, so that there are always some jars in the process of sterilization.

*Gauze* is the most valuable of all dressings for wounds, and in its preparation that variety is selected which has the greatest absorbent power. The gauze as it comes from the shops is first boiled in a solution of carbonate of soda, rinsed out, and dried; it is cut into sections of half a meter square of four thicknesses, folded into dressings, and half a hundred of these wrapped in a sheet and placed in the sterilizer under pressure for half an hour, the temperature being raised to 116° C., at the end of which time they are removed with disinfected hands and placed in a sterilized jar. These are known as sterilized dressings. Gauze sponges are made by taking pieces of gauze one-third of a meter square, rolling each piece loosely in the form of a ball, twisting the free end and tucking it in, and sterilizing as in the case of the dressings. These are kept in a separate jar. Marine sponges are never used, on account of the uncertainty of making them perfectly sterile, and the great risk of infecting wounds.

In the preparation of bichloride gauze dressings the gauze, after the initial boiling in soda solution, is soaked for twenty-four hours in bichloride of mercury solution 1:1000, wrung out, wrapped in a bichloride sheet and hung in the drying room. When dry it is spread out on the sheet, cut into pieces half a meter square, folded into dressings of four thicknesses each, and these put into a sterilized jar.

Probably the most tedious to prepare of all the gauze material is *iodoform gauze*, and after experimenting with numerous formulæ in its manufacture for a number of years, the present method was evolved, and the gauze is everything that could be desired and is absolutely sterile, with the iodoform evenly distributed in the meshes.

Ten pounds (3732 Gm.) of gauze is unwound from a roll, and having been boiled in a soda solution is cut into two-meter lengths and steeped for a period of twenty-four hours

in corrosive sublimate solution 1:1000, contained in a large stone crock. At the end of this steeping the future handling of the gauze must be done with the strictest regard for antiseptics. Before removing it from the crock the nurse sees that her finger-nails are scrupulously clean, scrubs her hands and forearms energetically with soap and water, and bathes them in alcohol; this is followed by a vigorous use of the nail-brush and bichloride solution, and she dons a sterilized operating gown. As much care is used in hand disinfection in the preparation of gauze as for the operation. A sterilized sheet is spread out on a table upon which are placed two sterilized bowls, into one of which an assistant pours three pints (1.41 liters) of absolute alcohol and into the other adds the ingredients for the emulsion—three pounds (1119.72 Gm.) of glycerin and one pound (373.24 Gm.) of iodoform which has been made sterile by dry heat—the necessary quantities for making up ten pounds of gauze. The nurse mixes the iodoform and glycerin by stirring with the hand, and adds the emulsion formed to the bowl of alcohol. The gauze is lifted from the crock, wrung out, and each of the two-meter lengths of gauze stirred in this mixture with the hands for one minute, and wrung out. The iodoform will have infiltrated itself into the meshes of the gauze, and this process is supplemented by rubbing the gauze for several minutes between the hands after it is wrung out of the mixture. It is folded lengthwise into narrow strips, rolled up like a bandage and each piece put into a small covered glass jar that has been made sterile. Each jar contains a single roll, and the gauze is laid in it in such a way that when the free end is drawn upon the gauze will unroll.

*Towels and sheets* are washed in warm water with oleine soap and are given numerous rinsings until all evidences of blood-stains are removed. After drying, parcels of two dozen towels each, wrapped in a small sheet, are placed in the sterilizer, remaining there for half an hour, the temperature of 116° C. being maintained. They are kept on hand in sterilized glass jars.

*Gauze pads* for abdominal operations are made as suggested by Ashton, of eight thicknesses of washed gauze nine inches square (22.9 cm.), with the edges tucked in and hemmed so as to prevent fraying; ten of these are wrapped in a towel and sterilized for half an hour in live steam under pressure; they are then put in a jar containing

three-per-cent. carbolic acid solution. When needed for operation, if time permits they are boiled in water for twenty minutes and allowed to stand in boiled water in a pan. In emergency cases they are given several rinsings in boiling water and kept in hot distilled water at the time of operation.

*Rubber protective* is used as a covering for dressings on a wound that discharges freely, in order to distribute the discharges throughout the dressings and to prevent infection from the air. It is washed in soap and water, scalded in hot water and kept in a jar containing three-per-cent. carbolic acid solution.

Although the object is to dispense with drainage, certain suppurating wounds, and very large wounds, make it desirable to use a *tubular drain*. These drains are made of soft india-rubber tubing and are used almost exclusively where a tubular drain is indicated; strands of silkworm-gut and iodoform gauze being used where smaller and capillary drains are needed. The tubing is washed in soap and water, cut into lengths, has holes cut in the sides, is rinsed and scalded and kept in a three-per-cent. carbolic solution, as bichloride of mercury will form chemical combinations with the rubber.

*Wet gauze bandages* are used to take a few turns over the dressing to hold it in place before applying the outer cotton bandage. Gauze is cut into strips eight yards (731.2 cm.) long and five inches (12.7 cm.) wide and sterilized. These strips are wound, after sterilization, on round wooden sticks five inches (12.7 cm.) long, after boiling them for one hour. The bandages thus rolled are kept in a 1:1000 bichloride solution in a glass jar.

Where abundant discharge is expected from wounds—as in an extensive dissection for removal of advanced carcinoma of the breast, or in general peritonitis in which, for example, bilateral drainage may be used—the primary gauze dressing next to the wound is supplemented by a large pad of *wood wool* of a size large enough to entirely cover the gauze. These pads are made by encasing a layer of wood wool one and a half feet (45.7 cm.) long, one foot (30. cm.) wide, and two inches (5. cm.) thick, with a single thickness of gauze to prevent the wood wool from separating. These pads are wrapped in small sheets and sterilized for one hour. They are folded and kept in covered sterilized jars. Absorbent cotton is required occasionally in dressing cases and is sterilized for half an hour in the sterilizer and kept in sterile jars. Gauze, however, has

supplanted its use to such an extent that it is seldom used except in fracture dressings.

Small *hand-brushes* made of hog-bristles mounted on wooden backs are the best instruments with which to accomplish mechanical cleansing of hands, instruments, and operative area. The substitutes that have been suggested and tried, as cotton, lamb's wool, excelsior, etc., have not proved entirely satisfactory. The utmost care is required in the cleansing of brushes lest they prove efficient carriers of infection. They are scalded in boiling water, and those for soap and water use are kept each in a small jar containing saturated solution of boric acid; and those for scrubbing with bichloride solution are kept in a jar containing this solution in 1:1000 strength. Two separate brushes are reserved for the patient, one for soap and water, the other for bichloride solution, and kept in the same way. All brushes used for mechanical cleansing from dirt after examination of the rectum, cancer of the uterus, etc., have *black* bristles, while the brushes used for scrubbing with bichloride solutions are made of *white* bristles. By this means no interchange of the brushes can be made. Brushes used in purulent wounds are destroyed after operation.

The preparation of *animal ligatures* has been a matter of most careful investigation for many years. All other material has finally been discarded in favor of catgut, which is undoubtedly the ideal ligature, but the manner in which it could be rendered absolutely sterile and still retain the peculiar properties required of it has been a bone of contention. Different methods have been followed in past years in its preparation, among them methods of Fowler and Leavens, by which catgut is kept in alcohol in sealed tubes; the preparation by formalin recently proposed by Senn; cumol catgut, etc.—all of which have finally been abandoned as unsatisfactory, in that the apparatus needed is expensive and troublesome, considerable time is consumed in the preparation, and the gut is less efficient as to strength and durability.

Mr. Johnston, of Jefferson Hospital, devised the method of preparation of catgut which has since been used and which has proved eminently satisfactory. Raw catgut, from the submucous coat of sheep's intestines, as obtained from the shops, is steeped in absolute ether entirely purified from sulphuric acid, to remove the fat,—light gut remaining twenty-four hours in the ether and the heavier gut forty-eight hours. When it

has been steeped a sufficient length of time in the ether the gut is transferred directly into a corrosive sublimate solution, consisting of mercuric chloride 40 grains (2.6 Gm.), tartaric acid 200 grains (12.96 Gm.), and alcohol 12 ounces (354.88 Cc.). The lightest weight gut should not remain in the corrosive mixture longer than from five to ten minutes, the next size from ten to fifteen minutes, and the largest sizes from twenty to twenty-five minutes. While the gut is being steeped and before it is transferred from the ether to the corrosive mixture, jars for keeping it ready for use are prepared by thoroughly scalding, filling them with an aqueous corrosive-sublimate solution 1:1000, allowing them to stand thus filled until the following day. This solution is then emptied and the jars nearly filled with alcohol (95 per cent. strength) and containing palladium bichloride in the proportion of  $\frac{1}{16}$  of a grain (0.0040 Gm.)—i.e., two drops of a palladium bichloride solution containing 15 grains (0.972 Gm.) of the salt to the ounce—to a pint of alcohol. By experiment it has been shown that more of the true bichloride of palladium will not stay in solution in alcohol, and when a precipitate occurs through excess of the palladium the whole goes to the bottom and is not again soluble in alcohol. The gut being lifted with an aseptic tenaculum from the bichloride mixture, is dropped into the prepared jars of palladium-alcohol and is ready for use. Catgut thus prepared is strong, pliable, and smooth, and keeps indefinitely as far as yet known. Careful laboratory experimentation by Dr. Coplin and Dr. Harris, and extensive clinical observation, prove the fact that it is sterile. When an operation is about to be performed the outside of the jar is rinsed with hot bichloride solution 1:1000, the glass stopper removed, and the mouth of the jar well wiped with the solution. The quantity of gut judged necessary for the operation is lifted from the jar by means of a sterilized tenaculum, and dropped into a dish previously sterilized and containing sufficient alcohol to cover the gut. If more gut is removed from the jar than is necessary for the operation the quantity left is immersed in the mercuric chloride solution for five minutes and transferred to the stock jar. This precaution gives absolute safety against infection.

When it is desirable to have ligatures or buried sutures remain intact for a longer time than it usually takes for them to be absorbed—the limit of this time being usually from five to six days—the gut is made more

durable by chromicizing it. It is steeped in absolute ether as before for twenty-four hours. Commercial ether contains a trace of sulphuric acid which ultimately softens and rots the gut, so it is not used. The gut is transferred to the corrosive-sublimate solution from five to thirty minutes, according to its thickness; it is then washed in pure alcohol to remove any deposit of bichloride of mercury, and transferred to a solution made by adding half a pint of absolute alcohol to an equal amount of sterile water in which has been dissolved five grains (0.324 Gm.) of bichromate of potassium. The gut remains in this solution eighteen hours, is rinsed off in alcohol, and dropped into a sterilized jar containing pure alcohol, in which has been dissolved one-sixteenth of a grain (0.0040 Gm.) of bichloride of palladium to the pint. This gut will last from fifteen to twenty-five days.

*Kangaroo tendon* is used in preference to catgut in certain cases, as in an operation for the radical cure of hernia where the several muscular layers are sutured to Poupart's ligament after the method of Bassini or Halsted. The tendon is here used on account of its greater permanence, as it is not absorbed for two or three months. The raw tendon having been soaked in absolute ether for forty-eight hours, is boiled at a temperature of 100° C. in alcohol for one hour. This temperature is maintained by means of a water-bath. It is then put in the mercuric chloride solution mentioned in the preparation of catgut for ten minutes, and kept in sterilized glass-stoppered jars containing bichloride of palladium one-sixteenth of a grain (0.0040 Gm.) to the pint of absolute alcohol. Pieces of the tendon thus prepared, placed on sterilized agar and gelatin and immersed in bouillon, have yielded no growth after numerous experiments by Dr. Coplin.

For suturing, silk, silkworm-gut, and silver wire are used. Silver wire is used principally in suturing bone in fractures and as a subcuticular stitch where stitch-hole scars are to be avoided. It is boiled with the instruments.

*Silk* of various sizes, received in skeins, is wound on glass spools, and several spools put in a test-tube which is plugged with cotton. The fractional method of sterilization is used when there is no urgent demand for the silk. The tubes are plugged with cotton and are placed in the sterilizer, a temperature of 100° C. being maintained for one hour each day for three successive days. At this

temperature on the first day all adult bacteria with which the surgeon has to deal are killed; on the second day the spores, and those spores which may have developed into full-grown bacteria, are destroyed; and on the third day any spores which may finally remain are sure to be destroyed. When, however, there is not sufficient time to follow this method the tubes are placed in the autoclave, which is a steam boiler in which the steam is locked up tight, so that a high temperature can be reached; it is kept in this for thirty minutes after the mercury has reached 116° C., and on removal is kept in the tube until needed, when the cotton plug is removed and the spools are dropped in a sterilized dish containing absolute alcohol.

*Silkworm-gut* is used generally in closing wounds with interrupted sutures. It is received in strands each one foot long; these are scrubbed with a brush and soap, rinsed several times in water and in alcohol, and immersed in bichloride solution 1:1000 over night. They are kept in absolute alcohol in a sterile glass-stoppered jar.

Cotton roller bandages are kept in a separate jar and sterilized by steam in the sterilizer; four different widths are used, from one to four inches (2.5 cm. to 10.2 cm.) each, eight yards (7.3 meters) in length.

In bone operations a small jar of Horsley's *wax* is always at hand, and its applicability is nowhere better indicated than in the oozing, sawn end of bone in amputations, the hemorrhage from which is controlled immediately it is applied; its value as an agent in controlling hemorrhage cannot be overestimated. It is made of seven parts of beeswax to one part each of almond oil and salicylic acid.

*Iodoform collodion* is used to seal small superficial wounds where it is possible or desirable to dispense with elaborate dressings, as after removal of a small sebaceous cyst from the face. A few thicknesses of sterilized gauze sufficiently large to cover the sutures are laid over the wound and painted with collodion, which acts as a thorough protective against atmospheric influences.

But one dusting powder is used in the clinic—*iodoform*—and that very rarely. It is sterilized by heat, and is not used as an active disinfecting agent, but as a drying powder in rare instances, where it will aid in absorbing secretions from a large granulating surface. Should infection occur it renders ptomaines harmless by forming innocuous combination with them, as shown by de Ruyter and Behring. Its use, however, is

limited almost entirely to tubercular cases, as it exerts such a decided antitubercular influence. The improvement noticed in these cases under its use is second only to the action of mercury in syphilis.

The various *antiseptic solutions* that are made for each clinic, and kept in large flasks, are solutions of mercuric chloride, carbolic acid, and boric acid. Mercuric-chloride solution is made by adding two drachms (7.39 Gm.) of the salt to a gallon of distilled water, as in other water the earthy substances combine with the mercury. This makes a strength of 1:500, and by adding hot water in equal amount to the solution at the time of operation it makes the standard solution of 1:1000. In order to distinguish it from other solutions it is colored red by adding a drop of a saturated alcoholic solution of eosin to a pint of the mercurial solution. A five-per-cent. carbolic-acid solution is known at a glance by its blue color, a drop of a saturated aqueous solution of pyoktānin giving it this color; this solution is also diluted one-half when used. Boric acid is kept in saturated solution and diluted to any strength desired when needed. Solution of sodium chloride, or normal salt solution, is made by dissolving six grammes of table salt in a liter of pure water, which is filtered through druggists' filter-paper into flasks; these flasks are plugged with cotton and sterilized by heating to a temperature of 116° C. for half an hour. It is used principally in irrigation in cavities, for hypodermoclysis and enteroclysis, and for intravenous injection in cases of shock or great loss of blood. For hypodermoclysis and intravenous injection the apparatus of Collin (see American Year-book of Medicine and Surgery, 1897, page 224) is used very advantageously; and for enteroclysis a rectal tube and fountain syringe are always at hand. There are also in readiness a Paquelin cautery adjusted for immediate handling, an aspirating apparatus, and tracheal tubes; splints, etc., and an outfit for bacteriological examination are kept in the adjoining room with the instruments.

*The Preparation of the Patient.*—The object of this is twofold: first, to put him in better physical health and raise the general tone of his system, thus increasing his tissue resistance to the invasion of infectious organisms; and second, by a series of local cleansings, in which the mechanical means is of the highest importance, to render surgically clean the area to be operated upon. It will depend upon the exigencies of the case whether the

period of preparation shall be a single day or can be extended several days, the latter being by all means preferable if the case be one of gravity and there be no special urgency. Especially will it be desirable to lengthen this treatment if the patient is suffering from any chronic organic disease in conjunction with his surgical ailment, allied conditions being not infrequently met with; and it is a matter of some gravity in certain cases to decide whether any operation is justifiable or not. As a rule in organic cardiac disease the valvular lesion does not contraindicate operation, and even the gravest of operations may be performed without any untoward results. In such cases the utmost care is taken in administering the ether, which is given in a minimum amount necessary to induce anesthesia, and the operation is done speedily—never, however, hastily. If there be serious advanced organic disease of the kidneys, an elective operation is withheld. If, however, surgical interference is necessary to save life—as in amputation for gangrenous extremities, a vesical calculus which is causing much mischief, or a cervical tumor which is encroaching upon the trachea—operation is performed with the aid of chloroform in spite of the nephritis. Chloroform anesthesia is used in these cases, as the weight of professional opinion leans in favor of it, and as shown in the tabulated list of anesthesia cases summed up by Dr. Da Costa.

The patient is given a hot tub-bath on admission, is furnished with fresh laundered underlinen and nightshirt, and put to bed. Confinement to bed prior to operation accustoms him to his unnatural experience, relieves him of the constipation and sleeplessness which always follow this change, quiets his heart and lungs, and keeps him in an equable temperature. If he be an excessive user of alcohol, stimulants are cut down to a safe dose; if he be a moderate user of spirits, however, the alcohol is cut off entirely. A saline is administered at once and repeated until the bowels are completely unloaded. Some time during the first day the resident surgeon takes a full history of the case, comprising in detail the family history, with especial inquiry as to any hereditary taint, the past history, and the history of the present illness, with a minute examination and description of the condition of special organs. The family history will aid in arriving at a definite conclusion as to the influence of heredity; the past history will disclose the patient's prior illnesses and his probable lia-

bility to infection; the history of the present trouble will give a detailed account of the cause, onset and development of the disease for which the patient has sought relief. The examination of special organs, heart, lungs, liver and kidneys will give the operator exact information as to the patient's general condition, and this is taken well into account and will have much weight in deciding as to what extent operation is feasible. Any unusual phenomenon, mental or physical, is noted in the history report under Remarks.

On the first day a careful examination of the urine is made by the anesthetist in person; this covers a reaction test with litmus, the specific gravity, a test for albumen and sugar. In testing for albumen, the acetic-acid test is used, which is made by pouring into a small test-tube half a drachm (1.8 Gm.) of a solution of equal parts of acetic acid and water, which solution is always kept on hand, and dropping into the tube a crystal of ferrocyanide of potassium, shaking it until the crystal is dissolved. The urine is then allowed to trickle down the side of the tube, and at the point of junction, if there be a trace of albumen, a white line will appear. If any albumen is found the amount of urine voided during the next twenty-four hours is collected, and a small quantity boiled and tested for the amount of urea present by the Doremus apparatus.

In testing for sugar Haines' solution is employed, which consists of a mixture of cupric sulphate 30 grains (1.848 Gm.), distilled water  $\frac{1}{2}$  ounce (14.79 Cc.), glycerin  $\frac{1}{2}$  ounce (14.79 Cc.), and liquor potassii 5 ounces (147.8 Cc.). One drachm (3.70 Cc.) of this solution is boiled gently, six drops (0.37 Cc.) of urine added, and if any sugar is present a yellowish-red precipitate will be deposited in the bottom of the tube.

A microscopic examination for blood or pus corpuscles, tube casts and crystalline or other deposits completes the urinary examination. Hemorrhage from the urinary tract will demand further investigation. A moderate number of hyaline casts will not be of any weighty significance or have any serious bearing against operation.

During the several days preceding operation the patient is kept under rigid ward discipline and a strict regimen and confined to his bed. On the first night the imaginative horrors of hospital life usually present themselves with unusual force, which keeps him wakeful and restless, so he is given fifteen grains (0.97 Gm.) of trional if necessary in

hot beef-tea, before the lights are turned low. The sound sleep which this potion induces has a beneficial effect upon the patient's nervous system, which is noticeable the following morning, when he will be found more cheerful and full of courage. If a tonic is necessary he is given two grains (0.13 Gm.) quinine sulphate and  $\frac{1}{10}$  grain (0.0022 Gm.) strychnine sulphate at regular intervals of four hours each or longer, and he is kept on light, easily digestible, nutritious food. The hot bath, which is a prominent factor in gaining excellent results in surgery, is repeated daily to stimulate proper skin action, and gentle massage produces a more active circulation, supplying to muscles exercise which requires no effort upon the part of the patient and is an excellent adjunct to the preliminary treatment which aims to improve his general condition. The application of these manipulations to the abdomen also increases peristalsis and induces a daily evacuation of the bowels—which it is extremely important should occur, for patients in whom the bowels are unloaded are less liable to infection—and the number of movements is recorded on a temperature chart, together with the quantity of urine secreted in each twenty-four hours. The morning and evening temperature is recorded on a Wilson chart, with the pulse-rate and the number of respirations per minute, so that the surgeon on making his daily rounds can infer on glancing over the chart what is the condition of the patient and whether there is any change from the record of previous days.

Up to this time the treatment has been only constitutional and moral. On the day before the operation attention is more especially directed to the local trouble for which the patient has sought relief. A series of local cleansings by mechanical rubbings and chemical disinfectants is now instituted, with the object of making the area surrounding the part to be incised or excised, an aseptic field. This disinfection is done twenty-four hours before operation by the head nurse of the ward and her assistant, or by the orderly and his assistant if it be a male screen case. These nurses have been thoroughly schooled in the methods and objects of asepsis and antisepsis, by the Resident and the Directress of the training school. Screens are thrown around the patient's bed, and the part to be operated on is exposed and surrounded by clean towels. The operative area is lathered with soap and brush, the soap is well rubbed into the skin with the hand, the hair cover-

ing it removed with a razor and the part rinsed off with distilled water as hot as the patient can bear it. A hot moist towel is laid over the part temporarily, while material is furnished for the further disinfection. From now on until the patient's final discharge from the hospital the strictest antiseptics is observed with all objects that come in contact with the operative field. The nurse scrubs her forearms and hands, paying special attention to her finger-nails, with soap and water and with alcohol, while her assistant wheels the small ward carriage in which are bottles of solution and jars containing dressings to the bedside, and pours out into two separate sterilized bowls a solution of bichloride of mercury 1:1000, in one of which the nurse scrubs her hands and forearms after using the alcohol, the other of which is reserved for the patient. Each bowl contains its own sterilized brush. The moist towel is removed from the patient and the area before mentioned rubbed with alcohol, the nurse using for this purpose a ball of sterilized lamb's wool enclosed in sterilized gauze. The assistant pours the alcohol on the part slowly as the nurse proceeds with the rubbing, and the assistant does not touch anything that will come in contact with the area being disinfected. After the alcohol rubbing the assistant removes the lid from the jar containing towels, and the nurse places a sterilized towel on each side of the area. The bichloride solution is then handed, and the part scrubbed fully five minutes with as much force as the patient will comfortably bear; it is dried with a sterile towel, pieces of corrosive gauze laid over the whole area and held in place by a bandage or binder adapted to the particular area,—a Scultetus bandage if the prepared part be the abdomen or back, the classical spiral if the part be an extremity. This completes the primary disinfection. The patient's bed is arranged tidily and the screens removed from around it.

The extent of the area that is thus cleansed will depend altogether upon its location and upon the gravity of the operation to be performed. A sebaceous cyst of the scalp, for example, would require shaving and cleansing of the growth and a limited area surrounding it, a towel properly placed at the time of operation protecting the operator's hands and instruments from coming in contact with the rest of the head; while a proposed craniotomy would necessitate cleansing and shaving of the entire head, neck and shoulders, including eyebrows and beard,

special attention being given to the external ear. A small fibroma of the breast where diagnosis is absolutely certain would require cleansing only of the mammary gland and immediate vicinity, while the removal of a carcinoma of the breast, whether involvement of the axillary glands be previously detected or not, or in a case of any mammary growth simulating malignancy and where positive diagnosis cannot be made before incision, would demand an extensive surgical toilet reaching from the line of the jaw to the level of the umbilicus and from the opposite shoulder to the middle of the back, including the arm of the affected side.

In operations upon the pubic, perineal and ischio-rectal or sacral regions in the female, the pubes, vulva and neighboring parts are shaved and cleansed, the vagina is scrubbed with a pledget of lamb's wool and a mixture of an ounce (29.57 Cc.) of the tincture of green soap to one pint (373.24 Cc.) of a two-per-cent. creolin mixture, followed by copious douches of warm sterilized water; this in turn by a boric acid douche three drachms (11.09 Cc.) to the pint. A bichloride dressing is then applied, and held in place by a broad T-binder. For douching the vagina the boric acid solution is used in preference to the bichloride solution, which is still used extensively in some hospitals but which does not exercise the slightest germicidal influence upon micro-organisms in the vagina, as Steffek has shown, and furthermore by irritation causes lessened tissue resistance and greater liability to infection, as Schimmelbusch has proved by actual experiment.

Operations on the rectum will require frequent laxatives and enemas beforehand, and at the time of operation a tampon of lamb's wool, with string attached to facilitate its removal, is pushed into the bowel, and located above the operative site in order to keep the intestinal contents from soiling the wound.

In abdominal operations the umbilicus will require special attention, and where the folds of the skin run down to such a depth that it is impossible to cleanse it thoroughly, it is covered by a wet bichloride mop, and at the time of operation iodoform collodion is poured over the umbilicus, shutting it off entirely from the operative field. In operations on the lower extremities it will often be a matter of considerable patience to thoroughly disinfect the skin of the feet, which usually are not bathed regularly by the class of patients who fill the hospital wards, and in order to get rid of the excrementitious matter, and

the saprophytic and pathogenic bacteria that are sheltered by the hard callous epidermis, a hot compress of weak bichloride solution surrounded by rubber dam is applied to the extremities after each daily bathing and allowed to remain. This is followed by scrubbing with the solution. The callous epidermis comes away by maceration after several such compresses have been applied. In operations upon the genito-urinary tract, besides the cleansing of skin, scrotum, and penis in the male, if necessary the bladder is irrigated three times a day with a solution of boric acid ten grains (0.648 Gm.) to the ounce, and salol and boric acid, each five grains (0.324 Gm.), are administered every four hours to disinfect the urine.

In operations in the mouth, pharynx, nose, or on either maxilla, the patient uses a mouth wash and gargle of a solution of boric acid and Listerine, every four hours, and uses a moderately stiff tooth-brush and precipitated chalk at least thrice daily. The nose and mouth are also thoroughly sprayed every two hours with a boric acid solution for two or three days.

The evening before the day of operation the patient is given two drachms (7.39 Gm.) of Rochelle salts, which dose is repeated early the following morning, and when the bowels have moved the rectum is flushed with a copious soap-and-water enema.

On the morning of the operation day he is given a hot sponge-bath in bed, followed by an alcohol rubbing. The dressings applied the previous day are removed, the disinfection repeated, and fresh dressings applied. He is not allowed to rise from the bed unless it be for evacuation of the bladder or bowels, as thus he will expend the least amount of vital force. A final enema of soap and water is given to thoroughly cleanse and empty the rectum, so that its mucous surface will be in condition to absorb, should extreme shock or excessive hemorrhage later on call for enteroclysis and the injection of stimulating enemata. A cup of tea or coffee or beef-tea is taken five hours before operation, and nothing else passes the lips, unless it be a small draught of brandy. He is given a suit of clean underlinen, a nightshirt, and loosely fitting cotton-flannel stockings which envelop the whole limbs and are tied loosely around the waist. The nurse removes any jewelry and false teeth worn by the patient, and at the stated time he is wheeled on a rolling table to the anesthetizing room.

[To be concluded.]

## THE VALUE OF CAMPHORIC ACID IN THE TREATMENT OF NIGHT SWEATS.

By H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

In the January issue of the *Edinburgh Medical Journal* my friend Dr. Ralph Stockman contributes a paper in which he notes the value of camphoric acid in the treatment of night sweats, and quotes considerably from foreign literature on this subject in support of his own clinical experience.

The writer of this article has on several occasions in papers which have been published, and every year to his class of medical students, emphasized the value of this remedy as an antisudorific. His first experience with it was in the wards of St. Agnes' Hospital during 1890-91, where he found, as Dr. Stockman has, that it controlled the sweats of tuberculosis in the great majority of cases and did not produce any disagreeable symptoms whatever, such as are usually caused by atropine or other powerful antisudorifics. He also in the first edition of his "Text-book of Practical Therapeutics," published in 1891, spoke of the value of this drug for this purpose, and in *The Medical News* of April 4, 1891, he contributed a paper in which he detailed two cases which had been markedly benefited by very moderate doses of the drug. He pointed out in this paper that twenty grains was usually quite sufficient to control the sweat, provided it was given early enough to be absorbed before the time of the sweat was reached; and he also pointed out, what other Continental observers had previously noted, that as much as sixty grains of this drug may be given without deleterious effect. A continued large employment of camphoric acid in the six years that have succeeded this report has still further confirmed his high opinion of this remedy. Like every other remedy, it will fail in some cases, but no remedy has been met with which in his hands so universally succeeds. It may be given in cachet, dissolved in whiskey or brandy, or placed in dry powder upon the tongue and washed down with a little water or milk; but as it is slowly absorbed it should be given an hour or two before the time at which the sweat usually comes on. The writer has also found camphoric acid of great value in the treatment of idiopathic pytalism as it is sometimes met with in young children, as it controls the salivation without disordering the digestion.

Box 470. DETROIT, MICH.

## Leading Articles.

### THE TREATMENT OF BRONCHOPNEUMONIA.

In the THERAPEUTIC GAZETTE for October, 1896, we published a leading article on the Treatment of Pneumonia in Children, and the frequent occurrence of this class of cases lends additional interest to the paper which Gaston Lyon contributes upon this subject to the *Revue de Thérapeutique Médico-Chirurgicale* of November 1, 1896, in which, after pointing out the gravity of the affection, and that in many cases it is a secondary complication of other diseases, such as measles, influenza, typhoid fever and similar ailments, he dwells upon its frequency in childhood and then discusses its treatment.

In regard to prophylaxis, he asserts that it is absolutely necessary that a patient suffering from the disease should be isolated in order to diminish the chances of other children in the same institution being infected; and further, that in the process of isolation care should be taken that children suffering from any one of the infectious diseases named should not be unduly exposed. He believes

that it is well to carry out rigid antisepsis in regard to the mouth and nasal cavities, and suggests that the recommendation of Marfan, of instilling several times a day an antiseptic liquid into the nasal cavities, should be carried out. Thus five or six drops of the following solution may be employed:

- Oil of sweet almonds, 1½ ounces;  
Menthol, 15 grains.

Or in other cases there may be employed:

- Vaselin, 1 ounce;  
Resorcin, 7 grains.

Or, in place of resorcin, guaiacol 15 grains.

This is to be applied to the nostrils as high up as possible with the finger. Nasal irrigations may be practiced in some very young children, using carbolic acid solutions in the proportions of 1:500, or resorcin in a solution of 1:100, and these solutions may also be used for washing the mouth—particularly about the gums—teeth and tongue. Sometimes it is well to rinse out the mouth several times daily with water which has been sterilized by boiling. In whooping-cough, influenza, measles, and other conditions associated with bronchitis, Lyon facilitates expectoration by the inhalation of aromatic vapors; he also sees to it that the child does not remain too long in one position so as to produce a tendency to hypostatic congestion. Care is also taken to render the intestinal canal antiseptic, as far as possible, as he believes that the *bacillus coli communis* may pass from the intestine into the lung and so produce secondary bronchopneumonia. For this reason the regulation of the diet in order to avoid any digestive disturbance is of the greatest importance. By these measures directed to the respiratory and alimentary tracts Lyon thinks that he distinctly helps in preventing the occurrence of bronchopneumonia as a complication of the diseases named.

In regard to the treatment of this disease in children, he believes that in the early stages of the affection the congestive process should be combated by revulsive measures and by the application of hot compresses or mustard plasters, or by rubbing the chest with oil or turpentine mixed with camphorated liniment, the skin being covered afterward by sheets of thin rubber. In other cases cold applications may be employed, but these are not so useful. If mustard poultices are used, care must be taken to prevent them from becoming cold and chilling the patient, and as mucus accumulates in the bronchial tubes,

particularly if it is in excess, he believes that it is well to give an emetic. For this purpose he thinks that ipecac is the best drug that we can employ. He generally orders the following prescription:

- ℞ Syrup of ipecac, 1 ounce;  
Powdered ipecac, 4 grains.

And gives two doses with a ten-minute interval. If the child is exceedingly feeble and it is not considered well to administer an emetic, the following mixture may be ordered:

- ℞ Syrup, 1 ounce;  
Syrup of tolu, 1 ounce;  
Cognac, 2½ drachms;  
Acetate of ammonium, 20 grains;  
Benzoate of sodium, 20 grains.

M.

One or two teaspoonfuls of this may be given every hour or every two hours according to the age of the patient. If the cough is excessive it may be well to add to this mixture from three to four drops of the tincture of belladonna or the tincture of aconite, but as a general rule narcotics and antispasmodics are not desirable in very young children. The air of the room in which the patient is lying should be moist, and it may be well, in addition to the steam which may be given off from the boiling water, to use steam which comes from the infusion of eucalyptus leaves to which has been added a little of the tincture of benzoin. In many cases, if constipation is present, it is well to give small doses of calomel, such as one-sixth of a grain, in order to evacuate the bowels and render them antiseptic. Drink should be given in abundance, particularly milk, as it facilitates renal activity. Fever is to be combated by the use of cold applied locally to the chest, or of tepid baths; or in other cases where sponge bathing is impossible, antipyrin may be used as in the following prescription:

- ℞ Antipyrin, 5 grains;  
Syrup of cinchona, 1 ounce;  
Syrup of eucalyptus, 1½ ounces;  
Peppermint water, 2 ounces.

A small teaspoonful every hour or two.

Or the following prescription can be employed:

- ℞ Distilled water, ¼ ounce;  
Simple syrup, 2½ drachms;  
Extract of licorice, 75 grains;  
Neutral muriate of quinine, 8 grains.

A small teaspoonful at a dose.

In other cases it is better to employ quinine in suppository, as neutral hydrochlorate of quinine 3 grains, coca butter 15 grains.

The following may be used by the subcu-

taneous method, with a hypodermic syringe, but is not generally advisable:

- ℞ Hydrochlorate of quinine, 30 grains;  
Distilled water, 2½ drachms.

Warm and give 10 to 30 drops at a dose.

As a stimulant it may be necessary to prescribe brandy or Malaga wine in small doses, or the following prescription may be used:

- ℞ Syrup of cinchona, ¼ ounce;  
Syrup of orange flower, ¼ ounce;  
Brandy, 1 to 2 ounces;  
Infusion of mint, 2 ounces.

A small teaspoonful as needed.

The alcoholic stimulant, if used, should be given at regular intervals. Should there be evidence of a failing heart and some cyanosis, minute doses of powdered digitalis or infusion of digitalis may be given three times a day, or caffeine associated with benzoate of sodium may be given by hypodermic injection. To combat asphyxia when it is imminent and to overcome nervous adynamia, Lyon believes that camphorated oil injections are of value; he gives ten to thirty minims of a ten-per-cent. solution of camphor and sweet oil hypodermically. Sometimes minute doses of powdered camphor rubbed up with sugar of milk may be given internally. In case of severe cardiac failure where an active stimulant is required, the following prescription is given:

- ℞ Sulphuric ether, 10 to 30 drops;  
Syrup of orange flower, 1 ounce;  
Syrup of tolu, ½ ounce;  
Linden water, 3 ounces;  
Mint water, ¼ ounce.

A teaspoonful of this mixture is given as frequently as needed.

In other instances where asphyxia seems imminent, the child may be plunged in a hot mustard-bath and remain there from four to five minutes. The bath is prepared by placing in it a small bag containing from three to five ounces of mustard flour. Whether it is wise to use the cold bath under these circumstances is doubtful, but some practitioners have been enthusiastic in its praise, particularly if there has been a tendency to hyperpyrexia; and in some cases Lyon asserts that its use in desperate illness results in "veritable resurrections."

The use of serum therapy, or the use of anti-streptococcus serum of Marmorek, is as yet uncertain, particularly as the infection is probably often a mixed one.

During the disease and during the convalescence the diet should be most nourishing

and easily digested, and as convalescence is about to be established it is well to make applications of iodine to the chest-wall or to aid in the absorption of exudations by counter-irritation. During convalescence any bronchitis which persists should be treated by the various balsams, or by one or two teaspoonfuls a day of a mixture of equal parts of syrup of tolu and syrup of turpentine. In the way of tonics to general nutrition, cod-liver oil and hypophosphite of lime is of advantage; and should there be any involvement of the tracheo-bronchial glands or emphysema, iodide of potassium is particularly indicated. Iron is also of value should anemia be present, prescribed in the dose of three teaspoonfuls a day of the following mixture:

- ℞ Syrup, 1 ounce;  
Syrup of terpine, 2 ounces;  
Syrup of iodide of iron, 2 ounces;  
Peppermint water, 2 ounces.

Good results also follow the use of arsenic in small doses. In the treatment of adults suffering from bronchopneumonia following these affections, it should be remembered that many of them are much depressed and gravely ill, and that alcohol, coffee, strychnine and kola are of value as rapidly acting stimulants. Digitalis and caffeine may also be needed. Cold baths are of doubtful value in some of these cases and tepid baths generally do better; indeed, these tepid baths are sometimes of the greatest possible service in relieving the patient. Should asphyxia and great dyspnea be present, injections of ether and caffeine are to be employed with sufficient frequency to produce good results. Care must be taken to insist upon sufficient nourishment being taken by the patient. Quinine and alcohol should be given, and a milk diet combined with digitalis and caffeine will also be of advantage.

---

#### *THE TREATMENT OF APOPLEXY.*

---

There are few conditions met by the practitioner of medicine in which the possibilities of treatment are so limited as they are in that condition which we generally term apoplexy, for although this term has been applied to a general train of symptoms, these symptoms may arise from several different causes, and unfortunately each and all of these causes have heretofore at least been largely beyond medical or surgical treatment. Within the last year there has been published in the

shape of a small volume an exceedingly valuable experimental research by Leonard Hill of London, upon the physiology and pathology of the cerebral circulation; and in its pages, in addition to finding much of great interest, certain thoughts are advanced which may be of value to the physician in the treatment of the conditions of which we are speaking. He points out that Falkenheim and Naunyn recommend that the blood-pressure should be kept up by every means in conditions of cerebral compression; while on the other hand Bergmann, with whom Hill is in accord, clings to the traditional treatment of lowering blood-pressure by depletion. After pointing out certain facts which support the opinion of himself and Bergmann, Hill goes on to emphasize the fact that depletion is only indicated when the arterial tension is high, and he reiterates the statement already made by Gowers that before depletion is attempted the diagnosis of hemorrhage should be reasonably certain, because in thrombosis, embolism, and acute cerebral anemia a loss of blood will only do harm by weakening the cerebral circulation. The question as to the differential diagnosis between the paralysis produced by hemorrhage, by thrombosis, and by embolism gains an additional importance from a therapeutic standpoint over and above its diagnostic interest, and while we have not as yet outlined any definite series of symptoms which will separate positively these conditions from one another, it will be remembered that there are at least a few manifestations which may point to the exact cause of the paralysis.

In the first place apoplexy, which is due to hemorrhage into the brain, is usually met with only in that class of patients who have attained such an age that their arterial walls are undergoing atheromatous changes, although of course the presence of a syphilitic history, or other causes which tend to produce such changes in the arteries, may result in hemorrhagic apoplexy during the earlier years of life. Again in hemorrhage into the brain consciousness is generally lost, and the compression of the lower centres in the brain which is produced by hemorrhage is apt to result in the development of vomiting and contracted pupils; and again, it is usually the case that in hemorrhage into the brain the systemic shock is more manifest and the febrile movement is apt to be greater than when the paralysis results from thrombosis or embolism. It is true, on the other hand, that thrombosis of the cerebral blood-vessels

is rather a condition of advanced age than of youth, and it is a noteworthy fact that thrombosis frequently comes on during sleep, whereas hemorrhage usually follows some exertion and frequently takes place after the ingestion of circulatory stimulants. The history of syphilitic infection producing an endarteritis would of course point to thrombosis quite as much as to hemorrhage.

The differential diagnosis of paralysis due to embolism from that due to hemorrhage is still more difficult, but should the physician find evidence of chronic or ulcerative endocarditis or their results, or other causes for the formation of emboli, the diagnosis would be rather in favor of such a cause than of hemorrhage. It is also a noteworthy fact that paralysis from embolus is more commonly met with on the right side of the body owing to the fact that it is more easy for the embolus to pass into the left middle cerebral artery than into the right. Having endeavored to the best of our ability, therefore, to make a differential diagnosis between these three causes of cerebral paralysis according to Hill, we have certain therapeutic procedures to undertake. If it is embolism or thrombosis it will as a general rule be a mistake to bleed the patient; while if the cause of the paralysis be hemorrhage, venesection is usually indicated.

Hill goes even further than this, and asserts his belief that in cases of paralysis due to hemorrhage it would be a justifiable experiment to open the skull-cap in order to relieve the pressure which is being exerted upon the brain substance through the leaking blood-vessels; and at the same time the depletion results in a fall of general blood-pressure so that hemorrhage ceases by the more rapid coagulation of the blood and the plugging of the artery, and death is put aside because the opening in the skull prevents the compression of the medulla, which Hill's experiments have proved to be so fatal.

In other words, intracranial hemorrhage may be reasonably treated on the same surgical lines as intracranial abscess whenever death is imminent from compression. Hill also emphasizes a fact which has been familiar to physicians for many years, but which has not heretofore rested upon such scientific evidence, that free purgation depletes the brain and causes a determination of blood to the abdomen; and, on the other hand, that the application of cold to the head fails to cause constriction of the cerebral or any other vessels.

## ON THE PREVENTION OF GONORRHEA.

This subject is suggested by a pamphlet published by Dr. Albert H. Burr entitled "Gonorrhea: Its Ravages and its Prophylaxis."

It has been the habit for years not only among the laity, but also in the medical profession, to regard gonorrhea as a troublesome, annoying, often painful affection, comparatively innocuous when considered in relation to syphilis, self-limited and only exceptionally producing crippling, invalidism, or death. As a matter of fact it is a disorder attended with a distinct ultimate mortality, and as a rule it persists in its contagious state for months, exceptionally for years; its remote consequences are as serious as those of syphilis, it is much more contagious, and it probably cripples or destroys many more individuals.

It is universally recognized that a large percentage of the pelvic troubles to which women are subject are due to gonorrhea. The majority of sterile, impotent and neurasthenic men thus suffer because of gonorrhea. Arthritis, endocarditis, peritonitis and pyemia may be caused by the gonococcus, and a large percentage of the blind in early life owe their malady to infection from this micro-organism. Burr calculates on the census of 1890 that 5480 people in the United States are totally blind from ophthalmia neonatorum.

The complications and sequelæ of gonorrhea are infinitely more serious, in so far as the numbers affected are concerned, than those following scarlet fever or any of the infectious diseases against the spread of which our boards of health so scrupulously guard.

It is evident, since gonorrhea is dependent upon a specific micro-organism which has been isolated, since in the vast majority of all cases it is conveyed only by sexual contact, and since the symptoms of both the acute and chronic stages of the disease are easy of detection, that vigorous legislation would be even more effective in preventing the spread of gonorrhea than it has proven in the case of other micro-organismal diseases which have been brought under control by quarantine and hygienic regulations.

It may be said without fear of contradiction that in the country at large not even the first blind groping step has been taken in the direction of stamping out this malady. Burr would limit the spread of gonorrhea by:

(1) Thoroughly educating the entire community in sexual hygiene and the dangers incident to departure from the moral law, this teaching being made a part of the curriculum of the public schools and to include public servants in all departments of industrial activity. (2) By allowing the official sanction of marriage only in case the contracting parties could show a properly attested medical certificate of health. (3) By having the laws of the country so amended that proof of transmission of venereal disease would constitute a legal ground for divorce. (4) By making the transmission of venereal disease an act exposing the guilty party to suit for damages or to imprisonment. (5) By having prostitution under medical control and posting means of prophylaxis after exposure in houses of ill-fame. (6) By prohibiting the drug-store treatment of gonorrhea.

Burr holds that the measures thus outlined are practical, and would largely decrease the ravages of gonorrhea.

These suggestions are worthy of careful thought.

As to the educational side of the question, this is a matter not to be disposed of lightly. It is undoubtedly true that both sexes should at some time receive instruction regarding sexual hygiene and the immediate and remote effects of venereal disease. The circumstances under which such instruction should be given, the age which children should reach before they are thus taught, and the selection of the proper persons to convey this knowledge, are all matters for serious consideration.

As to legislative enactments requiring that each candidate for marriage should file a certificate of health showing freedom from hereditary taint, infectious and venereal disease before license could be issued; this is admirable but impracticable; not because it would fail of accomplishing good, but because so large a percentage of the population would then become barred from matrimony that such a law could not be passed.

The amendment of the divorce laws so that conveyance of the disease after marriage would constitute a legal ground for divorce, would lead to infinite confusion and render still more lax our regulations governing wedlock.

Rendering it a criminal offense to impart a venereal disease would perhaps be of some service but would be open to the objection that only those who were utterly abandoned

and shameless would be likely to bring action. Under such circumstances the testimony adduced would be practically worthless, since it would usually have for its object the obtaining of money.

There can be no question that the drug-store treatment of gonorrhea should be prohibited.

The question of sanitary regulation of prostitution appears to be one for the public consideration of which this country is certainly not at present prepared. Powerful arguments can be brought not only from the moral but from the practical side against any such procedure. The posting of means of prevention in houses of ill-fame legalized by Government is not to be commended.

Dr. Burr is to be congratulated upon having discussed this subject in a true scientific spirit; even though his suggestions in the main seem impractical, his pamphlet will certainly direct thought in this direction, and ultimately some more or less efficient scheme of prevention may be evolved. One which from its educational aspect would be widely serviceable would be the adoption of a rule upon the part of the Government, railroad managers, and corporations employing large numbers of men, making a part of the examination of those applying for positions a careful investigation of the urine for pus, with rejection of the candidate in case this is found. This would call attention to the persistence of gonorrhea and would make many thousands more careful to avoid contagion and more systematic and persistent in pursuing treatment directed to the cure of the disease when it is once contracted. This, in conjunction with the suggestion made by Burr as to the instruction of young women and men in the public schools, would at least educate the community up to the point of being willing to recognize the existence of the evil and to set to work openly toward finding a practical method of lessening or entirely eliminating it.

## Reports on Therapeutic Progress

---

### THE TREATMENT OF COUGH.

The *Journal des Praticiens* of September 5, 1896, emphasizes the fact that cough, as a rule, is simply a reflex symptom due to respiratory irritation. Sometimes it has its origin in the larynx, sometimes in the trachea or bronchial tubes or even deeper in the lung.

For laryngeal cough, it is often well to

resort to the application of hot baths or sinapisms to the feet, the avoidance of conversation which would irritate the larynx, and perhaps the administration internally of some balsam or opiate or some feeble preparation of aconite.

In chronic laryngitis the cough may be much modified by the inhalation of steam, by the atomization of various medicinal substances, and by gargling with sulphur waters.

Should the cough seem to come from the trachea, and there be associated with it some retrosternal discomfort, a mustard plaster applied over the sternum will be of advantage, and it is well to administer night and morning a pill containing two grains of quinine and one-sixth of a grain of belladonna.

Should the cough arise from difficulty in the bronchial tubes or pulmonary vesicles, opiates combined with such nervous sedatives as cherry-laurel water, belladonna, or aconite, are useful; and if paroxysmal, it is well to add one of the bromides to this mixture. Should there be any expectoration, the employment of any of the balsams, such as the balsam of Peru or even the oil of sandalwood, is of advantage.

It should never be forgotten that cough sometimes arises from reflex irritation due to disease in the nose, the ear, the stomach, or the uterus. Usually such a nervous cough is laryngeal, and local applications or inhalations are practically useless. It is much better to resort to the bromides and to hydrotherapeutic measures. Valerian or the ammoniated valerian are useful under these circumstances. Sometimes, however, in place of nervous sedatives nervous stimulants are of value, and full doses of strychnine, as much as one-twentieth of a grain three times a day, do good. In rebellious cases it is sometimes most advantageous to subject the patient to a change of climate.

#### EFFECT OF PHOSPHORUS ON GROWING BONE.

KISSEL (*Virchow's Archiv*, bd. cxliv, I, 1896) records a series of experiments on dogs with phosphorus during the period of growth. The drug was given in small doses in oil, this method being selected as most near to the usual mode of administration to children. He finds that phosphorus has much stronger toxic properties than is generally supposed, and that a disturbance of digestion during the use of phosphorus, though apparently trivial, may have a fatal significance; ten

centigrammes per kilogramme of body-weight caused symptoms of chronic poisoning, with marked atrophic process, where bone was being deposited; six centigrammes per kilogramme hinders the normal development of bone; 3.3 centigrammes per kilogramme is the largest dose that can be given without harm. In chronic poisoning from quite small doses there was marked fibrosis, with shrinking of liver. No dose of phosphorus had any favorable influence on the growing bone. He concludes that there is no evidence in favor of the use of phosphorus in diseases of bone. —*British Medical Journal*, July 25, 1896.

#### THE APPLICATION OF COLD TO THE THORAX IN CHILDREN.

*La Médecine Moderne* of August 26, 1896, tells us that BERNARDBEIG of Havre obtains very good results from enveloping the chest of the child in cold wet cloths in the treatment of pulmonary affections associated with high fever, following the method recommended by Gendre, which has already been abstracted in the THERAPEUTIC GAZETTE. A piece of gauze, folded eight or ten times, and still of sufficient width to reach from the axilla to the umbilicus and to completely surround the thorax, is dipped in water at the temperature of the room, wrung out, and applied to the patient's thorax; over it is placed a piece of sheet rubber. The application is renewed, a second compress being in readiness, every quarter- or half-hour until there is a diminution of the dyspnea, the temperature, and the nervous excitation. As a rule, under its influence all these symptoms are markedly ameliorated and no complications occur. Should the temperature persist, the tepid or cool bath is resorted to. As a rule, after the first application the child does not object to their further use.

The compresses are indicated in acute hyperemia of the lung, with marked congestion and venous stasis, in cases of bronchitis, idiopathic or associated with the eruptive fevers. They are also thought to be of value in the treatment of chronic tuberculosis.

Bernardbeig cites cases which show the best results of his application of this treatment. An infant of fifteen months, who was attacked by bronchopneumonia, with a high elevation of temperature, intense dyspnea, and nervous excitation, improved with very extraordinary rapidity after this treatment was instituted. A little girl of two years, with a bronchopneumonia of rapid onset associated

with symptoms of suffocative catarrh, received these cold applications every half-hour, with marked amelioration of the grave symptoms and a modification of the dyspnea. Again, a child with bronchopneumonia, with marked dyspnea and elevated temperature, markedly improved after the fifth or sixth application. The very great advantage of this method of treatment is that the child's stomach is not disordered by the administration of remedies.

#### THE TREATMENT OF PERITONEAL TUBERCULOSIS.

The *Journal des Praticiens* of September 15, 1896, points out that peritoneal tuberculosis can be treated in several ways. In a certain number of cases surgical intervention is absolutely justifiable; and if there is ascites, opening the abdominal cavity often gives excellent results. On the other hand, it is not to be forgotten that in many young subjects peritoneal tuberculosis often disappears if the patient is put under good hygienic circumstances, receives proper tonics, has counter-irritation applied to the abdomen, and perhaps wears over the abdomen, in place of counter-irritation, an application of iodoform maintained in place by collodion. Simple puncture of the abdominal cavity, with drawing off of the liquid, also gives good results in some cases. In other instances it has been found that rectal injections of creosote were of value.

Thus, one case is quoted of a child of eleven years, whose sister and mother died of tuberculosis, and who was herself attacked in 1894 with enlargement of the bronchial glands, and early in 1895 with abdominal pain, loss of appetite, signs of pleurisy at the left base, and other evidences of tubercular infection; there was no vomiting, but the abdomen was large, painful, and markedly resistant to palpation. The treatment consisted in the regulation of the diet, which was largely liquid, and the application of ichthyol to the abdomen. Later on, from the 7th to the 16th of March, enemata of creosote in an emulsion of cod-liver oil, seven drops to five drachms of oil, were given; from the 16th of March to the 20th of April the quantity of creosote was increased to fifteen minims, and from the 20th of April to the 27th of May to twenty-two minims. At this time an attack of diarrhea necessitated an interruption of the treatment for several days, but up to this period the abdomen had diminished in volume, the hard resisting masses seemed to

have been reabsorbed so that the resistance was not so marked to palpation, and by the 25th of June the infant left for the country in a much improved condition, with normal lungs and good appetite; it had gained in weight and become free of pain. It is stated that by the 12th of April following the child was still in good health, had been subjected to the use of sea baths in the south of France, and was considered absolutely cured.

Another child, seven years of age, without bad hereditary antecedents, but who had been attacked with influenza and a severe bronchitis in 1890, was presented for treatment, with signs of right pleuro-pneumonia and general bronchitis, abundant expectoration, febrile involvement, but no abdominal symptoms. A month later, however, anemia was marked, there were signs of dry pleurisy at the right base, the breathing was bronchial, the left side of the abdomen swollen, the belly puffy, and the intestinal coils seemed to be agglutinated. Inunctions of ichthyol were used, and creosote injections in the dose of fifteen minims were resorted to. Under this treatment the symptoms of pulmonary and abdominal disease gradually disappeared, so that two months after the treatment was begun the abdominal condition was much ameliorated, although physical signs of trouble still existed at the right base. The child, however, which had weighed only 17 kilogrammes on the 10th of May, weighed 21½ kilogrammes on the 9th of September; its digestion was also greatly improved, and later on it was subjected to sea baths.

The third case was that of a young man of eighteen years, who was treated in the same way and rapidly improved.

#### LAVAGE OF THE STOMACH WITH SOLUTIONS OF NITRATE OF SILVER.

In *La Médecine Moderne* of September 16, 1896, an account is given of a method first employed by Forlanini in 1891, which consists in washing out the stomach in cases of excessive hydrochloric-acid secretion associated with chronic catarrh, first with pure water to which has been added in some cases a little soda, then with a liter of a solution of ten to thirty grains to the quart of nitrate of silver, which in turn is immediately followed by a solution of the chloride of sodium of the strength of thirty to forty-five grains to the quart in order to neutralize any excessive action of the silver solution. It is best to commence with a very weak solution of ni-

trate of silver, and gradually to increase its strength. Generally the best results are obtained from solutions of about fifteen grains to the quart. Under this treatment motor power of the stomach is greatly improved, and the quantity of liquid which remains in the organ after the repast is consequently considerably diminished. In one case the liquid diminished from 260 centimeters to 32. As a result, constipation is to a certain extent overcome and the general morbid symptoms disappear, among others vomiting; there is general systemic improvement, the patient gains in weight and muscular power, and nervous disorders and hypochondriasis disappear.

It is asserted that in the treatment of hyperchloracidity of a chronic type, with atony, these washings with nitrate-of-silver solution give better results than any other method of treatment yet tried.

#### THE TREATMENT OF SIMPLE GLAUCOMA.

HANSELL tells us in the *Philadelphia Polyclinic* of January 2, 1897, his treatment of glaucoma. He points out that simple glaucoma is essentially non-inflammatory in its origin, course, and termination as compared with true glaucoma in its acute and chronic forms. The main, if not the only, point of resemblance is the excavation of the optic nerve, and it is doubtless because of the presence of this diagnostic sign that the old classification has been retained. There is rarely in its history injection of the ciliary blood-vessels, pain, periodic loss of vision, or other evidence of acute increased intra-ocular tension. The diagnosis of the affection depends, in the main, upon two coincident conditions, namely, gradual diminution of vision, both central and peripheral, and slowly advancing cupping of the nerve-head. But spinal and idiopathic (no assignable cause) optic-nerve atrophy are characterized by similar symptoms. For this reason Schweigger suggested in 1891 that the term "simple glaucoma" should be accepted with considerable reservation. Increased tension, that *sine qua non* of glaucoma, cannot be demonstrated. The enlargement of the pupil is not dependent upon paralysis from pressure of the ciliary nerves that lie in grooves in the sclera, but is found only late in the disease, when atrophy of the nerve is far advanced. Recession of the near-point from failure of the accommodation is not a pro-

nounced symptom. A patient will require a stronger glass for reading than the healthy eye, but only because he needs magnification of the letters, that they may be perceived by the partly atrophic retina. It is not claimed that simple glaucoma should be classified among optic-nerve atrophies, although atrophy is one of its conspicuous features. It differs from them in that the cupping of the nerve-head is inconsistent with the advance of atrophy; that the disk is surrounded by a scleral or white, and not a choroidal or pigment, ring; that limitation of the nasal is more pronounced than that of the temporal field, and irregularly placed and sized scotoma are not infrequent; that it is favorably influenced by myotics and operation. This brief and imperfect enumeration of some of the facts that dissociate the simple or non-inflammatory type of glaucoma from the inflammatory forms and from atrophy of the optic nerve, and place it in a class by itself, are worthy of consideration in the projected treatment of every case. Great diversity of opinion may be found in the writings of clinicians as to the efficacy of the various remedies. Some, among whom may be mentioned Cohn, Abadie, and Simi, agree that the daily use of solutions of eserine sulphate is indicated. The first writer claims to have retained full acuity of vision and normal fields for a period of fourteen years. On the other hand, Nettleship urges iridectomy without delay, and Ramsey as soon as the diagnosis is established. Wicherkiewicz recommends first eserine, then sclerotomy, finally iridectomy. Our own experience is opposed to immediate iridectomy, for the following reasons: (1) Iridectomy on one eye has been known to precipitate an attack of acute glaucoma in the second eye. (2) In order to be of value the artificial pupil should include one-fifth of the iris. The astigmatism consequent upon the corneal incision and the irregular refraction of the extra-pupillary portion of the lens is detrimental to good vision. It not infrequently happens, also, that cortical opacities of the lens coexist with simple glaucoma. (3) Malignant glaucoma, rather indefinitely described by Schweigger, and accurately defined by Friedenwald as a painful and nearly always incurable blindness following the operation of iridectomy for glaucoma, may be encountered. (4) Eserine, a painless application that may be continued for years without danger, is of indubitable value.

The brief history of a case that has been

under observation for five years will serve to illustrate the efficacy of eserine and the uncertain value of iridectomy. Mr. S., aged fifty-two, complained in 1891 of diminution of vision for far and near. Right 20-30, left 20-50, brought to the normal by low-power minus cylinders. Both disks were cupped over their entire surface. The fields were concentrically contracted, but only moderately so. Until very recently vision and fields have remained unaltered through the use of one-half grain solutions of eserine, applied once daily, and the patient has been able to use his eyes without discomfort. A few weeks ago the eserine seemed to have lost its power. Double iridectomy was performed. The healing in the left eye progressed without incident. On the second day after operation on the right, vision was totally abolished in that eye for a short time. The wound was closed, and the anterior chamber reestablished, and the eye very slightly congested. Under hourly instillations of one grain solutions of eserine vision returned to its previous acuity in two days. Here, then, is an instance of retention of vision for four and one-half years by the constant use of eserine, and of an acute glaucoma precipitated by iridectomy.

#### THE TREATMENT OF ULCER OF THE STOMACH BY SUBNITRATE OF BISMUTH IN VERY LARGE DOSES.

We learn from *La Médecine Moderne* of September 9, 1896, that KRAMER has reported very good results from the use of massive doses of subnitrate of bismuth in gastric ulcer after lavage has been gently employed, until the water left the stomach perfectly clear and transparent. He injects into this organ a mixture composed of six drachms of subnitrate of bismuth in 200 cubic centimeters of warm water. In the course of five or six minutes the bismuth is deposited over the entire surface of the stomach. These applications are made every two days until a cure is effected, as little food being given by the stomach as possible. The results are said to be remarkable, and in no instance were symptoms of intoxication by bismuth produced. Thus, in nine cases the cure was most rapid; in two others the results were not so good. Altogether, as much as 100 to 200 grammes of bismuth may be used in this manner, without danger of producing symptoms of intoxication. It is needless to add that the bismuth must be absolutely pure. [The only objection to this plan of treatment is that it neces-

sitates the dangerous procedure of introducing a stomach-tube in cases of gastric ulcer.—ED.]

#### THE TREATMENT OF ATROPHIC CATARRH.

In the *Medical Record* of January 2, 1897, Dr. JOHN NORTH of Toledo gives the following interesting directions for the treatment of this troublesome affection: The first thing is to clean the nasal cavities of all crusts and to see that they do not form again. Without thorough cleanliness nothing can be done to cure atrophic catarrh. There seems to be a prevailing opinion among physicians that atrophic catarrh cannot be cured; that all that can be done is to keep the nose free from crusts and give the patient temporary relief. Our books and teachers tell us that this is all that can be done.

After a number of years' experience in the treatment of atrophic catarrh the writer is prepared to say that not only can it be relieved but it can be cured in almost every case. It will take long and persistent daily treatment, extending over from one to three years. It is not necessary for the physician to make the treatment during all this time. With proper appliances the patient will be able to do most of the work, calling on the physician only once a week or once in two or three weeks. For the first few weeks the physician should make the treatments.

The crusts should not be removed by force. An atomizer should be used with an antiseptic and alkaline solution. Dobell's solution or some of its modifications can be used for this purpose. Seiler's tablets answer a good purpose, but the writer prefers the following:

- ℞ Resorcin,  $\frac{1}{4}$  drachm;  
Sodium bicarbonate, 15 grains;  
Sodium borate, 15 grains;  
Glycerin, 1 ounce;  
Aqueous extract of hamamelis, 2 ounces;  
Water, enough to make half a pint.

The writer has a tablet made containing five grains of resorcin and two grains each of bicarbonate of sodium and borate of sodium. One of these tablets is dissolved in one ounce of water, or, still better, in a saturated solution of hydronaphthol.

One of the foregoing solutions should be warmed and the nasal cavities thoroughly sprayed with it at least once every day. After the solution has been used thoroughly, the parts should be sprayed with warm vaselin containing ten drops of campho-menthol

and five drops of eucalyptol to the ounce. This treatment should be persisted in till all the crusts come away and are prevented from reforming. Then the patient is ready to commence active treatment. If the case is a mild one and not too far advanced, resorcin is one of the best applications to use. The resorcin wash should be used and then the nasal cavity thoroughly sprayed with vaselin and resorcin (one per cent.). As resorcin is insoluble in vaselin, it is first dissolved in hot glycerin and then mixed with the vaselin; in some cases thymol is also added in the proportion of five grains to the ounce. This treatment will clean the cavities thoroughly, act as a disinfectant, and promote the growth of healthy tissues. In old advanced cases, in which the membrane has atrophied to such an extent as to appear like parchment, with little or no secretion, the writer gets better results with judicious use of trichloroacetic acid.

There is no remedy in the entire *materia medica* that is so useful in the treatment of all nose and throat troubles as trichloroacetic acid. Dr. Stein, of Moscow, says that in solution of from 1-to-500 to 1-to-2000 it will keep all suppurative processes in abeyance for a week. In weak solution it is one of the best antiseptic remedies that the writer has ever employed, and it also causes stimulation to atrophic membrane to a greater extent than any other application with which the writer is acquainted.

Dr. Stein says: "Weak solutions of trichloroacetic acid used in the nose in simple atrophic rhinitis for a considerable time sometimes produce such a decided hypertrophy of the turbinated membranes that it may become necessary to cauterize them in order to secure free breathing. No other medicine of which the writer is cognizant produces such a remarkable effect, and thus this agent is particularly applicable in the treatment of *ozena*. In true *ozena* he now applies stronger solutions than he did at first—*i.e.*, one-half to ten per cent. The odor is not so quickly nor so thoroughly abolished by any other medicinal agent as by the acid. Here it is certainly a specific."

From his use of trichloroacetic acid during the past six years North agrees with Dr. Stein in every particular. He keeps a number of solutions of the acid on hand, varying from one to fifty per cent. After the nose is thoroughly cleansed with the resorcin solution, the part is dried with absorbent cotton, and then a two-per-cent. solution is applied on a probe with cotton to the diseased mem-

brane; the strength is increased as the effect becomes less active, spraying afterward with the vaselin and resorcin.

We sometimes find a portion of the mucous membrane entirely denuded of epithelium and in which the glands are all destroyed, leaving a thin, dry layer of membrane covering the bone. In these cases the treatment mentioned will not stimulate the part nor cause new epithelium to cover the atrophic part; it is therefore necessary to stimulate the edges of the diseased part and cause the mobile leucocytes to collect at or near the edges. In time the entire surface becomes covered over with a thin mucous membrane, which after a further interval becomes thicker and furnishes sufficient moisture to prevent the formation of incrustations. In treatment of these cases he follows the method of the horticulturist when he finds a tree denuded of its bark—*i.e.*, blazing. Nature has made an effort to repair the injury by throwing out a secretion around the edges, which organizes and partially covers up the denuded surface by the formation of a thin bark. At this time the horticulturist scratches the edges of the thin bark and nature covers up still more of the surface. If this is continued, in time quite a large space will be covered up with this thin bark, and gradually it becomes thicker and almost removes the appearance of injury.

The writer proceeds as follows: He cleans the part thoroughly with the resorcin solution; then takes a twenty-per-cent. solution of trichloroacetic acid and applies to the edges of the atrophic space, not allowing it to come in contact with any other portion of the membrane. This produces slight irritation and causes the nutrient pabulum of the blood and also the mobile leucocytes to collect beneath the coagulated rind formed, and to become organized under its protection. The part should be well covered with solid vaselin and resorcin. If this treatment is followed up from time to time, the part, if not too large, will become completely covered, and the membrane be capable of performing at least a portion of its function. He has treated a number of cases by this method with good results.

#### LIQUID MALT PREPARATIONS.

The *Journal of the Boston Society of the Medical Sciences* for November, 1896, contains the following note by HARRINGTON on liquid malt preparations:

Twenty-one different brands of liquid malt

extract were obtained and analyzed. That they were not true malt extracts is shown by the fact that in no one was the slightest diastasic power; all were alcoholic, some being stronger than beer, ale, or even porter. Six contained less than three per cent., five contained between three and four per cent., four between four and five per cent., two between five and six per cent., three between six and seven per cent., and one over seven per cent. of alcohol. In food value they proved to be about equal to heavy beers and porters. In a number of specimens a large amount of salicylic acid was detected, the largest amount being found in one which claims to have been "made in Germany."

#### GALL-STONES AND THEIR MEDICAL TREATMENT.

In the course of quite an extensive article on this topic published in the *Intercolonial Medical Journal* of Australia of October 20, 1896, R. B. Duncan points out that the medical treatment of gall-stones is eminently unsatisfactory from whatever point it is regarded. It is quite true that, during the paroxysm, we can generally afford relief by means so well known that they need not be alluded to. The real question arises as to our ability to act on the gall-stones themselves, and rid the patient of their dangerous presence. Is it possible for us either to prevent the formation of the stones themselves, to effect their solution, or to promote their discharge? There is no doubt whatever that timely and careful treatment can do much to prevent the formation of biliary calculi, but the writer's experience leads him to believe that we are seldom consulted at a stage when our efforts in this direction would be of much avail. If we are called upon to treat such a case, then exercise undoubtedly is to be warmly commended, not taken indiscriminately, but graduated exercise after meals; this favors the flow of bile at a time when its secretion is most active. Perhaps of scarcely less importance is massage in the neighborhood of the gall-bladder and common duct. If these measures are supplemented by warm alkaline baths, a sufficient amount of attention will have been paid to the hygienic aspect of prevention. No treatment can be of much avail, from this point of view, unless strict attention is paid to the diet. Bearing in mind the causes which may lead to an excess of cholesterin in the bile, and also the condition of the bile favorable to its deposi-

tion, one or two important principles may be laid down. Meat, for instance, should be taken in the strictest moderation, and fats and sugars at the same time entirely excluded from the dietary. Moderation must also be observed in regard to farinaceous substances. Two articles of this nature are singularly unsuitable, namely, peas and carrots—the former containing a substance similar to cholesterin, and the latter a form of vegetable cholesterin itself. It is not often, however, that we are able to anticipate the formation of such concretions by any such advice, as cholelithiasis is generally a recognized fact when our opinion is sought on the matter.

The purely medical treatment of this affection has at all times excited a considerable degree of interest, and the remedies recommended at one time or another have been more distinguished for quantity than efficiency. It would serve no useful purpose were we to enumerate the various remedies that have been recommended in this affection. There cannot be any possible doubt that a course of alkaline treatment has been attended with benefit, not only in expulsion of the stones, but in preventing their formation. The histories of such Spas as Carlsbad, Vichy, Ems, Kissingen, and others, afford ample evidence on this point. It must be remembered, however, that such a course of treatment combines the use of alkaline baths as well, and a rigid dietary. Whilst this is of no practical value to practitioners far removed from these resorts, still the lessons that such courses of treatment inculcate can be to a certain extent imitated. An alkaline course of treatment renders the bile more alkaline and watery—a state conducive to the disintegration of stones already formed, and to their prevention. Whilst there can be no doubt as to the beneficial action of alkaline mineral waters, their mode of action would seem to be chiefly that of expulsion, as careful examination of stones passed under such a course of treatment shows little or no chemical action. This statement, however, still wants elucidation. The experience gained at some of the above mentioned resorts is conclusive as to the curative value of such waters if taken over a long period of time and repeated at intervals. When it is desired to imitate the action of the above mineral waters, the bicarbonate of sodium and sulphate of sodium may be used, separately or in conjunction. Their method of administration will depend on so many circumstances that it is unnecessary to enter into particulars. It may be

said, then, that alkaline remedies, administered under such conditions, remove "acidity of the stomach, correct any congestion of the liver that may be present, and render the biliary secretion more watery and alkaline." By this means formation is anticipated, and when this has taken place the stones are acted upon chemically, and their expulsion also promoted.

There are one or two subsidiary remedies that demand a passing notice. Much attention has been paid at times to a remedy composed of three parts of sulphuric ether and two parts of oil of turpentine. Of this, the patient should take four grammes every morning until 500 grammes of the mixture have been taken. This remedy has, in some instances, received unqualified praise, and in other instances has been as unsparingly condemned. Some of its beneficial action is ascribed to its antispasmodic effects. The most extravagant claims have been made regarding the solvent action of chloroform on gall-stones, but these have not stood the test of time and experience.

A remedy which is largely used at the present time is olive oil. Opinions regarding it are extremely conflicting. The writer has tried it repeatedly, but with absolutely no success except in one instance. As the case is rather a striking one he reports it. The patient was a lady sixty-two years of age, and extremely stout. The diagnosis of her state was rendered easy by the early discovery of gall-stones in her motions. He has never had a case in which the suffering was so severe—indeed, terrible. During the paroxysms she was rendered almost frantic, and large doses of morphine had to be administered to give her relief. Every likely remedy had been tried in vain, and more for the sake of doing something than because of any benefit that was expected, olive oil was ordered. Its administration was commenced during a paroxysm, and the effect was nothing less than marvelous. From the moment of its administration the symptoms rapidly subsided, in the course of a few days disappeared altogether, and have not since returned, a period of nearly twelve months intervening. Soon after she began to take the oil the patient declared that she was passing large numbers of stones. An examination easily disproved this statement. She was passing numbers of concretions certainly, but they were not gall-stones. In this instance a beginning was made with two ounces of the oil twice daily, rapidly increased to half a pint.

The oil was taken without a single drawback, and the relief was immediate and permanent. Of its mode of action little is known, but it is thought to act chiefly as a cholagogue.

#### DIAGNOSIS OF PUERPERAL INFECTION.

B. C. HIRST, in the *University Medical Magazine* for November, 1896, writes a valuable paper on this subject. He directs that an antiseptic vulvar pad should be worn during the continuance of the lochial discharge so as to protect the genital orifice from contact with the atmosphere; and the materials of which this pad is composed, or rather the antiseptics with which it is impregnated, should be chosen with a view of keeping the bloody discharge from decomposing should it soak through the pad, and thus be exposed to atmospheric contamination. The best materials for this purpose in the writer's experience are salicylated cotton and carbolyzed gauze.

The water for douches, if they are employed, or for washing off the vulva and perineum, may be the source of fatal infection. All the water used about a puerpera should be boiled beforehand for at least half an hour. It is not sufficient to make a germicidal solution—as for example of corrosive sublimate—in the belief that all germs in the water are killed by the antiseptic employed. Tetanus bacilli will live for hours in a 1-to-4000 bichloride of mercury solution, and the other antiseptics usually employed in obstetric practice,—lysol, kresol and creolin—may be perfectly inert against many dangerous pathogenic germs during the time that usually intervenes between the preparation of an antiseptic solution and its use upon a patient. He has seen three women contract tetanus from intra-uterine douches of unboiled water (creolin two per cent.) during a time when the water of Philadelphia was unusually turbid in consequence of freshets in the Schuylkill Valley.

The puerperal woman may be infected by disease-germs carried upon her person, especially in the pubic region; by her personal clothing, by the bedclothing and mattress, by the vulvar pads and the pads upon which the buttocks rest, by the material used to wash off the vulva and perineum, and especially by pathogenic bacteria lodged in the vaginal or uterine mucous membranes before labor or even prior to conception.

To insure the greatest obtainable degree of personal cleanliness, the woman falling in

labor should be given a full bath, special attention being paid to scrubbing the genital region most thoroughly with soap, hot water, and a soft bristle brush or a wash rag. After the bath the woman should put on clean clothes throughout. The mattress on her bed should not be soiled by the discharges of previous labors, by urine, feces, or other putrescible matter. It should not have been used in any case of contagious or infectious disease, and it should be protected by a rubber cloth that has been carefully scrubbed clean. The bedclothing should be clean, the bed being freshly made up for the labor. The pads on which the buttocks rest during labor and afterwards should be made of nursery cloth, prepared in the way described in the writer's directions to the nurse (boiled and dried). It is scarcely necessary to say that a pad when soiled should be thrown away and not used again. The vulvar pads should be made of carbolized gauze and salicylated cotton, the best materials for disinfecting a bloody discharge. The nurse should make them up with sterile hands as they are required, or, if she makes a number at a time, they should be wrapped in a clean towel and taken out for use with sterile hands. The materials used to wipe off the genital orifice, the mouth of the urethra, and the perineum should be absorbent cotton soaked in a 1-to-1000 solution of sublimate for at least a half hour before its use. During the second stage of labor these pledgets of cotton are employed to wipe away feces as it emerges from the anus, always in the direction from before backward.

Care must be exercised to remove blood and blood-clots from the vulva before putrefaction sets in. This is best done by placing the woman on a bed-pan, letting a stream of boiled water run over the parts, and if necessary using cotton to wipe them off. This should be done about six times in the twenty-four hours, for the first four or five days, and then two or three times a day until the discharge ceases.

A careful examination should be made of every woman's vaginal discharges in the beginning of labor. If there is leucorrhoea or any pathological condition of the vaginal secretions, the vagina should be thoroughly scrubbed out with tincture of green soap, hot water, and pledgets of cotton, and should then be douched with a bichloride of mercury solution 1-to-2000, a little clear water being employed at the end of the douche to wash out any residual sublimate solution that

might poison the patient, or do harm to the infant's eyes in its descent through the birth-canal.

It should be borne in mind in the conduct of the labor that excessive bruising, long-continued pressure of the maternal tissues, extensive injuries, all conduce to microbic invasion of the parts by reducing their vitality and by affording, through solutions of continuity, a ready entrance into the system. The proper conduct of labor, therefore, is an extremely important item in the preventive treatment of puerperal sepsis.

Finally, in the management of the third stage of labor and of the early puerperium the greatest care should be exercised to evacuate the uterine cavity of all putrescible matter, and to secure as far as possible firm contraction of the womb. The presence of dead foreign matter within the uterine cavity will pretty surely attract saprophytes, and an imperfect involution of the womb will favor the direct invasion of the uterine sinuses and blood-channels by micro-organisms, and the absorption of the products of microbic activity into the circulation and into the lymph-spaces.

The physician should not carry infectious germs upon his person or clothing into the lying-in chamber, and he should be scrupulously careful not to insert pathogenic germs into the woman's vagina in the course of his examinations. If a general practitioner is in attendance upon infectious and contagious diseases, he should either give up obstetric practice entirely, or, if he cannot do so, he should take a full bath and should change his clothing completely before attending a woman in labor.

It is a wise precaution to carry in one's obstetric bag a long linen gown, or a pair of duck trousers and a cheviot shirt. The change of clothing should be made in another room before seeing the patient at all, or at any rate before making an examination.

In the preparation of his hands for an examination the method recommended by Fürbringer is to be preferred. This consists in a ten-minutes scrubbing of the hands with a nail-brush, hot water, and tincture of green soap, followed by a most thorough scrubbing with alcohol, and this followed by immersion of the hands in a 1-to-1000 bichloride of mercury solution for at least two minutes. The examining finger should then be anointed with carbolized vaselin (five per cent.), and in making the examination the vulvar orifice should be exposed by lifting up the

upper buttock as the woman lies upon her side so that the finger can be inserted directly into the vagina without becoming contaminated by being swept over the skin near the anus or pubes while searching for the vulvar orifice. As every examination entails upon the woman some risk of infection, they should be limited in number as much as possible. The best results ever obtained in obstetrical practice as regards both morbidity and mortality have been secured by an almost entire elimination of the vaginal examination, which has been replaced in the practice of some enthusiasts by abdominal palpation, and even by rectal examination. It is unnecessary, however, and is moreover inadvisable, to give up the vaginal examination altogether. Much may be learned by abdominal palpation, so that there is little necessary information to be gained by examining per vagina, but there are some conditions that can be learned in no other way. A few vaginal examinations in the course of labor are therefore indispensable. No harm is done by these if their number is restricted, and if sufficient care is exercised to secure perfect cleanliness of the hand, and to conduct the examination in the way described above.

The nurse should adopt the same precautions in regard to personal cleanliness that have been recommended for the physician. She should not have come from a contagious or infectious case. She should put on fresh clothing throughout for attendance upon the obstetrical patient. She must take a full bath, scrubbing her hair and scalp well with soap and water, and rinsing her hair in a 1-to-1000 sublimate solution, which is then washed off with pure water. Her hands should be carefully prepared according to the method above described before any manipulations of a patient's genital region or of her breasts. It would be her duty, also, in the care of a puerpera, to enforce the sanitary and aseptic regulations already described under their appropriate heads.

All implements to be used about the person of the parturient and puerperal woman should be boiled for at least five minutes. In the case of a few articles that might be injured by boiling water, a bichloride solution 1-to-1000 should be employed for their disinfection; a full half-hour at least being allowed for the immersion, and the bichloride solution being made up with boiled water.

The treatment of puerperal sepsis is both local and general. Locally, a thorough dis-

infection of the whole genital canal is called for in every case of puerperal infection. It may appear unnecessary, and may prove on actual experience to be even harmful, but no one can tell beforehand how necessary this procedure will be. In the vast majority of cases it will be productive of the greatest good. It is only occasionally useless and very rarely actually harmful. It should, as already stated, invariably precede all other treatment for puerperal infection. The method of disinfecting the genital canal may be described as follows: a double tenaculum, a large, dull curette, a placental forceps, and an intra-uterine catheter are boiled for fifteen minutes. The operator disinfects his hands and arms. The patient is placed in the dorsal posture across the bed, with her buttocks resting on a rubber pad. The external genitalia and the vagina are scrubbed with tincture of green soap in hot water, and pledgets of cotton; the vagina is douched with a sublimate solution, 1:2000. The operator then seizes the anterior lip of the cervix with the tenaculum. An intra-uterine douche—sublimate solution, 1:2000—at least a quart, is administered. Then with the curette and the placental forceps in turn the uterine walls are gone over thoroughly in all directions, six to twelve times, till nothing is brought away but bright blood; a second intra-uterine douche concludes the treatment.

If the womb is flabby and large, with a tendency to flexion, so that the drainage of the uterine cavity is not good, he recommends packing the cavity with iodoform gauze. He has found it of advantage in the majority of cases to pump into the uterine cavity by means of a Davidson's syringe and a two-way catheter a mixture of two drachms of iodoform and two ounces of sweet oil.

In addition to cleansing the uterine cavity in the manner described, the operator should take the opportunity of carefully inspecting the visible portion of the parturient tract, and if on the cervix or in the vagina there are false membranes or areas of inflammation and localized infection, these should be carefully treated; best by the application of a strong solution of nitrate of silver, a drachm to the ounce.

It may be necessary to repeat the intra-uterine douches several times—in fact, several times a day for many days; in this case plain water only should be used. Nothing whatever is gained by the employment of strong chemical disinfectants which cannot

always reach and destroy the infecting micro-organisms of the genital tract, but which do have a most depressing action upon the body-cells of the walls of that tract, reducing their resisting power against the invasion of attacking bacteria.

It is rarely necessary to repeat the curettage or the use of the placental forceps. It may be advisable to provide drainage from the uterine cavity by the insertion of a strip of gauze to the fundus. This is only necessary, however, in those cases of flabby, relaxed wombs which fall forward on themselves in such a manner as to prevent the free exit of the lochial discharge.

The general treatment is stimulating. The patient should have as much food of an easily digestible character—chiefly milk—as she can digest, and as much alcohol as she can consume without showing the physiological effects of it. Digitalis will be useful as long as the pulse is above 110; strychnine may be combined with it in suitable cases. To tide the patient over emergencies, carbonate of ammonia in large doses by the bowel, and nitroglycerin hypodermically may be required. Inhalations of oxygen may be of service. Absolute rest and freedom from all disturbances, mental and physical, must be insisted upon, and the patient should be given the best nursing that the family can afford.

#### *A CASE OF ASPHYXIA DUE TO ETHER ABSORBED FROM THE STOMACH.*

LOROT reports in *La Tribune Médicale* of November 25, 1896, the following case:

A girl aged 9½ years was admitted to the Hospital Tenon in a state of asphyxia. The face was pale, the lips blue, and the whole appearance of the patient that of exsanguination. The extremities were cold, the fingertips were also pallid. Auscultation revealed no respiratory sound, no cardiac bruit, and there was absence of the pulse. It was found on investigation that the patient had taken a large quantity of ether internally.

Artificial respiration was resorted to and massage of the precordium was tried, with no result. There was an abundant muco-watery secretion in the mouth and the tongue had been injured by the spasmodic contraction of the jaws. Rhythmical traction of the tongue was resorted to; cold applications were made to the forehead and the neck; flagellations, friction and stimulation of the intercostal nerves were also tried. After about twenty-five minutes a single respira-

tory movement took place. The respirations then became irregular, the heart's action somewhat violent and tumultuous, the pulse became stronger and extremely rapid; color returned to the skin and heat to the extremities. Whenever the treatment was interrupted, however, the respiration ceased and the patient returned to a comatose condition. The conjunctiva was without a reflex, the eyes wide open, and the pupil dilated, but slight tonic movement of the left side occurred. Thus there was a unilateral grimace of the face, contraction of the arm and leg on the left side with tremor; the right side was immovable. These tremors of the left arm ceased on inhalations of ammonia being given. Finally, the patient returned to consciousness with a gradual passing away of the symptoms that we have named. Lorot believes that the method of Laborde—namely, the application of rhythmical tractions of the tongue—saved the patient's life.

#### *TREATMENT OF LARYNGEAL TUBERCULOSIS.*

In an article in the *Cincinnati Lancet-Clinic* of December 5, 1896, S. E. ALLEN states that although a large per cent. of our cases of laryngeal tuberculosis cannot be cured, all can be alleviated, and treatment must have in view the desire to alleviate if a cure cannot be brought about. We must not abolish therapeutic methods, even if a cure is out of the question.

Any general plan of treatment of the affection under consideration can be divided into three heads: (1) The treatment of the general system. (2) Absolute rest of the parts—measures instituted to keep the larynx absolutely at rest. (3) Local measures.

The general treatment is the same as that of tuberculosis elsewhere. By tonic remedies, good feeding, and climatic influences, we seek to strengthen the resistance of the cells to the invasion of the organism; and just as such treatment can bring about a cure of pulmonary tuberculosis, so it can bring about a cure of mild laryngeal disease. The climatic treatment is our mainstay in pulmonary tuberculosis, and I am inclined to believe that it, with the methods considered under headings 2 and 3, will be found to render the greatest service in laryngeal tuberculosis. If the bacilli are deep in the tissues they cannot be reached except by most energetic surgery, and our only hope is that we can increase cellular resistance and prevent further exten-

sion. Fresh dry air and sunlight, proper food, and healthy exercise of mind and body, together with proper local treatment, will often work wonders in this disease.

Absolute rest of the parts will be found one of the greatest aids toward curing laryngeal phthisis. General and local methods will often fail if the patient cannot be made to stop using his voice. This is a point too little insisted upon. Movement of any abnormally irritated part lowers the vitality of the cells of that part, and so movement here depresses cellular vitality and allows increased bacterial development. Use of the larynx in speaking must be stopped, and also those movements caused by coughing. The cough arising from the laryngeal trouble and the concomitant pulmonary disease must be checked if good results are to be expected. This relief can be brought about by morphia, codeia and the like, but such remedies are bound to lower cellular vitality and to undo what we seek to gain by constitutional treatment. There is no surer or better way to relieve the cough of laryngeal tuberculosis than by the use of menthol; one-half to one drachm of a mixture of camphor and menthol, five grains each to the ounce of albolene, injected directly into the trachea from a laryngeal syringe, if possible, or into the larynx alone if we cannot drop the solution past the vocal cords, has a remarkable effect on the cough. If it is impossible to make these injections, a much less marked result can be obtained by inhalation of the vapor of the same mixture. Should the lungs be markedly involved, with considerable purulent expectoration, menthol, guaiacol and albolene make a good injection. The menthol and guaiacol injections have a local antiseptic action, and under the influence of these mild remedies many cases of beginning tubercular ulceration can be cured.

We come now to the consideration of local measures. These can be classified into:

Simple antiseptic, non-irritant applications;

More active germ and tissue-destroying agents, including lactic acid applications;

The use of electrolysis and the galvanocautery; and, lastly,

Excision of diseased tissue with curette or cutting forceps.

Among non-irritant, simple applications the best are menthol inhalations, iodol and iodoform insufflations, and pyoktanin applications. In cases of slight severity, with the best hygienic treatment, these remedies often suffice to bring about a cure. Lactic acid is

properly considered the best remedy for promoting the healing of tubercular ulceration, and is applied in strengths varying from twenty per cent. up to the pure acid. Lactic acid probably has more cures to its credit than any other remedy.

In all cases where we have a tubercular infiltration without ulceration, or where the ulcer is deep, the lactic acid cannot be expected to exercise the healing action which it has on superficial ulcerations, and it is here that surgical procedures must precede its application. It is from a surgical treatment of the trouble that we have obtained the most startling results. Since the introduction of ordinary surgical methods tubercular laryngitis has to a certain extent ceased to be the hopeless, terrible affliction of former years. Up to the year 1883 it was thought that tubercular destruction in the larynx never cicatrized, that such a thing as a cure was impossible. In that year Krause demonstrated on a post-mortem specimen cicatrices he had brought about with lactic acid; the desire to get the lactic acid solution on to the seat of the trouble led to curettement and removal of the infiltration. Excision of tubercular masses and curettement of ulcerated surfaces is, in selected cases, a procedure that cannot be recommended too highly. This, with the subsequent application of lactic acid, has often a wonderful effect.

Relapse and progressive destruction of course are very often met with; nor is this to be wondered at when we remember the nature of the disease. If these methods do not cure in all cases, they nearly always serve to alleviate the distressing symptoms. The excision of an inflamed and sensitive epiglottis or ary-epiglottic fold will relieve dysphagia as nothing else will, and is to be recommended even when there is no hope of a cure. Where the symptoms complained of are not particularly distressing, and from the nature of the pulmonary trouble no hope of recovery can be entertained, aggressive surgical interference can hardly be recommended. Reaction to surgical interference is slight, as a rule, and it is often surprising to see how quickly healing takes place.

When the disease causes marked stenosis it has been found better to perform tracheotomy than to try to remove the obstruction through the natural passages. After tracheotomy the enforced rest often causes a marked subsidence of the infiltrations. Some have even recommended tracheotomy as a means of curing laryngeal phthisis.

In advanced cases we often can do nothing more than alleviate with opiates if pain is constant, with cocaine if pain is present only on swallowing.

---

*THE TREATMENT OF PERITONEAL TUBERCULOSIS BY PUNCTURE AND LAVAGE WITH HOT STERILIZED WATER.*

In the *Journal des Praticiens* of November 28, 1896, is an article with this title, in which attention is called to the fact that DEBOVE has employed puncture, followed by lavage with a saturated hot watery solution of boric acid, with success in a number of cases. He has been followed by Caubet and Baylac in similar instances by the employment of puncture and irrigation, except that these latter clinicians have employed sterilized water a little above the temperature of the body. They claim by this means that all the advantages of a laparotomy are obtained without exposing the patient to the dangers of that operation, and that the employment of pure hot water is safer than the use of a liquid containing a medicinal substance. The heat exercises a useful influence upon the peritoneal wall, upon the activity of the leucocytes, and upon the capillary circulation in these parts. Should there be much fluid in the peritoneal cavity before the operation it should be withdrawn by ordinary paracentesis before the lavage is attempted. They also think that this method is particularly valuable in chronic fibrinous peritonitis with ascites.

*A REPORT ON ANARCOTINE.*

In the *British Medical Journal* of September 26, 1896, SURVEYOR makes a report on this substance.

The work was undertaken to determine the influence of the alkaloids of opium, chiefly anarcotine, on metabolic changes produced in animals. At one time, before the introduction of quinine, this alkaloid was largely used as an antiperiodic. In India, however, as stated by Sir William Roberts in his presidential address before the Pharmacological Section of the British Medical Association, it has now been altogether discarded.

The general impression at present about the value of the drug is that it is a harmless principle of opium. Experiments were performed to determine its effect in diminishing or increasing metabolic changes in dogs. Blood-pressure experiments were also per-

formed on dogs. However, it was found that a subcutaneous dose of the chloride of anarcotine, even to the extent of four grammes, had no effect on the blood-pressure or the heart. The respiratory movements of the animals were not altered. Respiratory changes of gases before, during and after injection of the chloride were studied in mice. It was found that a subcutaneous injection of 0.016 gramme of anarcotine chloride per body weight of 100 grammes produced diminution of the amount of CO<sub>2</sub> given off by the animal; the amount of oxygen absorbed was also slightly diminished. The respiratory ratio was not much altered. The animals lost weight during administration of the drug, which was soon regained on stopping it.

Administration of pure anarcotine to dogs in doses of one gramme produced vomiting within half an hour. The smallest dose required to produce this effect was 0.5 gramme per body weight of five kilogrammes.

Anarcotine chloride (one gramme) produced slight retching in one dog, while subcutaneous injections of the salt up to four grammes in an anesthetized animal did not produce any effect.

It is curious that a perfectly tasteless alkaloid like anarcotine should produce vomiting, while its chloride, which is extremely bitter in taste, can be tolerated to a greater extent.

The chloride was prepared from the alkaloid by the action of just enough hydrochloric acid. The resulting salt was dissolved in distilled water, filtered, evaporated down to dryness, dissolved in chloroform, and crystallized out from the chloroform solution by the addition of anhydrous ether. The crystals were redissolved and recrystallized salt used for the experiments.

As regards the effect of the alkaloid on metabolism, great difficulty was met with in the matter of diet. Some dogs refused to take the ordinary dried meat, so it was ultimately decided to feed them on sterilized meat. Minced meat was weighed in small beakers, and these sterilized at 120° C. in the autoclave. During the administration of the drug the animals lost weight, and the nitrogen absorbed was found to be diminished; in one case it fell to one-third the normal amount. The amount of fat absorbed was also diminished to some extent.

The amount of water excreted as urine did not appear to be regularly influenced, however; as a rule it was increased, and on some

occasions it was found that the total amount of water excreted both as urine and in feces was in excess of the amount taken on the corresponding day. This observation requires further study before one can venture to state anything definite about it. There was slight diminution in the amount of nitrogen excreted by the kidneys.

The metabolic changes after the administration of hydrochlorate of morphine were studied in one dog. The dose given was 0.05 gramme to 0.02 gramme per five kilogrammes body weight. In this case the animal was very restless; it took very little food, and lost weight; the amount of weight lost, however, did not correspond to the nitrogen and fat excreted during the same period. In fact, although very little food was taken, the weight lost was not considerable. This can be accounted for in this case, and also in cases of anarcotine experiments, by the fact that the amount of nitrogen excreted by the kidneys was also diminished to a great extent.

---

*THE USE OF SEDATIVES AND HYPNOTICS IN THE TREATMENT OF INSANITY.*

In the *British Medical Journal* of September 26, 1896, OSWALD, in opening the discussion on the use of sedatives and hypnotics in the treatment of insanity, commented on the very different views held as to the usefulness of sedatives by alienists and on the degree and frequency with which they were prescribed in different asylums. He believed that a drug-induced sleep was often bought at too high a price; and he regretted that in the construction of asylums more attention was not paid to specially arranged rooms where all the external causes of sleeplessness would be minimized. He regarded any indication of failure of strength as the chief symptom making urgent the procuring of rest in acute cases, and laid special stress on the necessity for making sure that the absence of sleep was not due to some peripheral irritation. Taking acute cases generally, his experience led him to prefer paraldehyde. It had no bad effects, and it tended to restore the broken sleep-habit. It had a slightly diuretic action as well, and did not depress. He had given it hypodermically in two cases without local inflammation following. It was unfortunate that in the rush for new drugs so many of the older sedatives and hypnotics had been forgotten. How often was conium juice prescribed now, and was digitalis as

often used as its calmative power undoubtedly deserved? He believed it was one of the dangers to guard against—namely, that of falling into the habit of using one or two sedatives to the exclusion of others. Chloral, especially when combined with one of the bromides, was most useful as a day sedative—a term to which he took exception. It might not be as effectual as sulphonal, but its bad effects were fewer. The bromides, when combined with cannabis indica or hyoscyamus, could be pushed to much larger doses than were generally given, and were powerfully sedative. Sulphonal he used as seldom as possible, believing that its action was accompanied in many cases by a destruction of the red blood-corpuscles. The belief that its administration produced a mild dementia was a growing one. Its value in chronic mania was undoubted, but its use tended to mind-weakening; it cut short periods of excitement, but the patients did not regain mental clearness. Morphine was not so useful as opium, and his experience of hyoscine and hyoscyamine was not favorable. He confessed he had failed to come, in a very limited experience, to any definite conclusion regarding the use of these drugs. Useful they were, but not nearly so essential to the treatment of patients in an insane hospital as many supposed. A diminution in the frequency with which they were prescribed would lead to the development of other means for treating the symptoms for which they were given. They were not the best hypnotics and sedatives. These were found in exercise, work, distraction of thoughts, amusement, and such like, but the scope of the discussion did not include these. In the treatment of the insane in private houses their use could often not be avoided, and if they did—as he believed—in many cases retard recovery he saw in that a strong argument for the treatment of mental disease in asylums. In asylums when they had to be used he preferred a pure hypnotic like paraldehyde or alcohol, and in other cases chloral with bromide, or bromide with cannabis indica. Sulphonal he never gave without feeling that he might be setting up a morbid condition over which he would have little control.

---

*REPORT ON THE ACTION OF DRUGS ON THE LEUCOCYTES OF THE BLOOD.*

GEORGE WILKINSON, in the *British Medical Journal* of September 26, 1896, records the results of his studies on this subject. He

points out that during recent years several observers have recorded certain changes which take place in the number of the leucocytes of the blood of animals after the injection, either subcutaneously or directly into the circulation, of bacteria, bacterial products, nuclein, peptone, and other substances. Acting on the suggestion of Professor Boyce, he has performed a series of experiments with a number of drugs, which were administered to rabbits by hypodermic injection, with the object of observing any changes that might occur, not only in the total number of leucocytes in the circulating blood, but also in the relative proportion of the mononuclear and polynuclear varieties.

The following drugs have been used in the experiments: Potassium iodide, pilocarpine nitrate, atropine sulphate, digitalin, carbolic acid, turpentine, camphor, antipyrin, quinine hydrochlorate, salicin, and sodium salicylate. With each drug several experiments were made and various doses employed. Blood was obtained by pricking the animal's ear, and after dilution with Toison's solution the corpuscles were counted with the Thoma-Zeiss apparatus, every precaution being taken to avoid fallacy. The corpuscles were counted immediately before, and at various intervals after, each injection; and at the same time cover-glass preparations of the blood were made and afterwards stained, usually with eosin and hematoxylin. From the latter the proportion of mononuclear to polynuclear forms was estimated by counting from 300 to 500 leucocytes.

The general results of the experiments may be stated thus: The first effect of the injection is to cause a diminution in the number of leucocytes per cubic millimeter. The degree and duration of the diminution varies with the drug employed, but with all those mentioned above, unless the dose was very small, its occurrence was recognized when the blood was examined sufficiently early. As a rule it was not of long duration; but a notable exception occurred in the case of one of the experiments with quinine hydrochlorate. A large dose (0.7 gramme) of this drug caused death of the animal two days after the injection; the blood was examined frequently between the time of injection and its death, and on every occasion the scantiness of the leucocytes was very striking. Coincidentally with the diminution in the total number of leucocytes, there was a distinct increase in the proportion of the mononuclear to the polynuclear varieties.

Following the diminution there was observed in the case of all the drugs employed an increase in the number of leucocytes per cubic millimeter. This change did not occur in the above mentioned experiment, in which a very large dose of quinine was administered, but with smaller doses of this drug its occurrence was noted, although, as with salicin and salicylate of sodium also, the degree of increase was slight in comparison with that which followed the injection of the other drugs. With nearly all of them the increase was a much more evident phenomenon than the preceding diminution, and was of much longer duration. It was further constantly distinguished by the fact that the polynuclear leucocytes were relatively more increased in number than the mononuclear forms.

With atropine, and also with pilocarpine, a series of injections were made on one animal at intervals of twenty-four hours for several days. The leucocytes were counted immediately before, and at frequent intervals after, each injection. The first injection of each series was followed by a diminution in the leucocytes per cubic millimeter, which again was rapidly succeeded by a marked increase. The latter had not passed off at the end of twenty-four hours, when the next injection was given, but the sudden fall which followed each injection was very striking, as were also the coincident changes in the relative proportions of the mononuclear and polynuclear leucocytes. Indeed the alterations were so distinct that they could be recognized almost by a glance at the stained films, which were made at the same time, without counting at all. These changes in the number and relative proportions of the leucocytes are analogous to those which have been described by several observers as occurring after the introduction into the circulation of bacteria, bacterial products, etc. Sherrington has described similar changes in the blood of dogs and cats as the result of acute local inflammation.

The writer has also observed certain changes in the structure of the leucocytes under the influence of repeated doses of pilocarpine. Two grains of this drug was given hypodermically every twenty-four hours for seven days to one rabbit, and for fourteen days to another. Numerous cover-glass preparations of the blood were made at different times of each day, and they were stained in series by different methods, care being taken that all the specimens of a series were exposed to stain-

ing fluids of the same strength and for the same length of time. These specimens exhibit a remarkable change in the structure and staining reaction of the small oxyphile leucocytes. The cells of this variety in the normal rabbit are full of very definite granules which stain readily with eosin and other acid dyes. Under the influence of the repeated doses of pilocarpine the granules became gradually less distinct, and eventually the protoplasm appears perfectly homogeneous and takes up the stain very feebly. In one of the animals this change was found to be very pronounced in so short a time as fifteen minutes after the first dose of the drug. The reaction of the nucleus of this variety of leucocyte to nuclear stains becomes diminished in a corresponding degree. On the other hand, the large oxyphile leucocytes with coarse granules (Ehrlich's eosinophile cells) show no change whatever, and stand out in marked contrast to those of the other variety. The red blood-corpuscles are also unchanged.

#### THE TREATMENT OF VOMITING IN TUBERCULOSIS.

In the *Revue de Thérapeutique Médico-Chirurgicale* of December 1, 1896, MATHIEU is reported to have recommended the employment of the following treatment in this troublesome condition. He first points out that the vomiting largely depends upon the fact that the stomach is reflexly irritated from the pneumogastric nerve by the diseased condition of the lung. For this reason small pieces of ice or one to two teaspoonfuls of chloroform water may be given every ten minutes for several days, to allay gastric irritability after food is taken. After the meal the following mixture may be given:

℞ Menthol, 3 grains;  
Syrup, 5 ounces.

The chloroform, however, constitutes the most efficacious form of medication.

In the discussion which followed Mathieu's paper, Ferrand stated that he had gotten the best results from diminishing the sensibility of the pharynx by the application of ten-per-cent. solutions of bromide of potassium in glycerin.

#### SUCCESSFUL CÆSAREAN SECTION AFTER DEATH.

There can be no doubt that the aim of the obstetrician is to save both mother and child. When there is any difficulty about the rescue

of both, the mother must first be considered. When the mother is already dead the child is usually dead also, but this is not invariably the case. The medical attendant should certainly save the child if he can, but for obvious reasons he may be prevented, especially in private practice. The patient's relatives may well feel more respect for a corpse than solicitude for an unborn infant. Yet it is well to remember and to remind them that the child may be saved. In the obituary notice of Dr. Harley, mention was made of his success in saving a child after the mother's death. The patient was suffering from mitral obstruction and aortic regurgitation; there was anasarca, but it would appear the urine had only been tested once, ten days before death, and no albumen was detected. The kidneys were found "full size and quite healthy." On April 25, 1850, the woman, in the beginning of the ninth month, had a fit of dyspnea in the kitchen of the Edinburgh Royal Maternity Hospital. Harley, then house surgeon, diagnosed spasm of the glottis, and performed laryngotomy. The dyspnea increased, and he was beginning the operation of tracheotomy when the patient died. He immediately tore through the patient's dress, opened the abdominal wall and the uterus, seized the child by the leg, and delivered it. It was in a state of suspended animation; cold water, inflation, and artificial respiration revived it, and the cord was cut. The child was a male weighing 6 pounds 12 ounces, and measuring 18½ inches. Not more than twenty minutes elapsed from the time the patient was seized in the kitchen till all was over, including the stitching up of the abdominal wound and the removal of the mother's body. The child not being premature was easily reared, and grew up to manhood. A very interesting case of successful post-mortem Cæsarean section has recently been reported by Sandberg, of Christiania. He operated under very unfavorable conditions, as the mother had died of eclampsia, an affection very perilous to the fetus. The patient was a primipara aged thirty-six, and expected her confinement on September 20, 1895. In July of the same year anasarca set in. On August 18 she died comatose, after numerous attacks of eclampsia. Four minutes after the heart sounds had ceased, Cæsarean section was performed. The uterus was opened after the escape of much ascitic fluid. The child was born asphyxiated, but breathed well a quarter of an hour after delivery. It was under four pounds in weight, and not sixteen inches long. Placed

in an improvised couveuse, it was fed with a mixture of one part milk, three parts water, and four per cent. sugar of milk. The infant was successfully reared, and was living in October, 1896, when the report was published. This remarkable case of the delivery and rearing of a truly posthumous child is a triumph for the couveuse as well as for the well-timed operation for which Dr. Sandberg deserves credit. We have already noted its ethical bearing, an interesting question for medical jurisprudence. As Spiegelberg has pointed out, Roman law directed that before the corpse of a pregnant woman was buried Cæsarean section should be performed. By Prussian law, the performance of Cæsarean section on a woman who has died during pregnancy is left to the judgment of the medical attendant in the particular case. Löwenhardt and others advocate the operation when the mother is in *articulo mortis*, but though this doctrine is based on a high principle, it is contrary to higher sentiments, and does not find favor either with the profession or the public.—*British Medical Journal*, Nov. 28, 1896.

#### THE CONTRAINDICATIONS TO THE USE OF THE SALICYLATES IN ACUTE ARTICULAR RHEUMATISM.

CHASSEVANT contributes a paper with this title to *La Semaine Médicale*, No. 54, 1896. He points out that according to Jaccoud the salicylate of sodium is contraindicated in those cases of acute articular rheumatism in which there is a predominance of visceral complications. Under these circumstances Jaccoud prescribes tartar emetic in large doses, and if necessary adds opium to the dose in order that the patient may withstand it, thereby checking the diarrhea and tendency to vomiting. The result of the use of this remedy is usually a fall in the fever, the quieting of the nervousness, and never when it has been instituted has Jaccoud met with pericarditis or cerebral accidents of a serious character.

Chassevant asserts that a number of other physicians sustain this clinician in his assertion that the visceral phenomena are benefited. He quotes Donald Hood's paper, published in 1881, in which 350 cases of acute articular rheumatism were treated by the salicylate of sodium. Out of these 350 cases, 241, a proportion of 80, suffered from cardiac complications.

Smith in 1882 published the statistics of 1724 patients suffering from polyarticular

rheumatic fever treated in various ways. Of this number five per cent. had cardiac complications.

#### THE USE OF ENTEROCLYSIS IN THE GASTRO-INTESTINAL AFFECTIONS OF NURSINGS.

An interesting article upon this topic is contributed by THIERCELIN to the *Revue de Thérapeutique Médico-Chirurgicale* of December 1, 1896. After a historical review of those who were the first to employ this method he passes on to a consideration of its therapeutic effects, its indications and its contraindications. He believes that it is indicated in cases of obstruction of the bowels and in cases in which fermenting materials have been retained in the intestine, whether this condition be acute or chronic, although he believes that it is particularly useful in the chronic cases. By the use of enteroclysis under these circumstances the fermenting material is removed and the poison which is formed thereby is washed out of the bowel. Should fever accompany the infectious process cold water may be employed for the injections, using as large a quantity as one or two quarts. These copious irrigations of the bowel are one of our best aids for the relief of the hyperpyrexia which seems to menace the child, and speedily cause a fall of temperature amounting to 2° to 3°. On the contrary, should the affection be accompanied by collapse and a fall of temperature, the employment of water at a temperature of 100° to 102° or 102.5° is generally useful in raising the temperature of the patient to the normal. When fever is present the injection improves the condition of the pulse and the action of the heart, and it is probable that a sufficient quantity of the liquid is absorbed to increase the function of the kidneys and liver, thereby producing a true lavage of the entire system. The liquid which is employed in different morbid states consists of water which has been carefully sterilized by boiling and to which common salt has been added in the proportion of 100 grains to the quart of water. Should there be present a follicular enteritis it is well to use a decoction of marshmallow root. Other authors recommend in cases of acute infection of the bowel in nurslings the employment of a solution of boracic acid; and still others, notably Doria, a solution of lactic acid. It is also to be remembered that alkaline injections of large quantities of water are of value in the treatment of catarrhal

jaundice. The total quantity of the injection varies with the age of the patient. Rarely in nurslings do we exceed the employment of two quarts, but in adults as much as five quarts of liquid may be used once or twice a day. Contraindications to the employment of enteroclysis are cardiac affections and ulceration of the bowel to such an extent that there is danger of perforation, although it has been claimed by some physicians that they have gotten good results from the employment of enteroclysis in the treatment of typhoid fever. Thus Doriac has obtained a rapidly beneficial influence by the use of large injections of a hot solution of creolin.

In cases of intestinal obstruction, enteroclysis is useful but must be employed with caution. The apparatus which is necessary for this treatment is a reservoir capable of containing two quarts of liquid, to which is attached a long rubber tube, at the extreme end of which is placed a gutta-percha nozzle about one foot in length, the diameter of which varies with the age of the patient. This nozzle or catheter is gently introduced into the bowel for a considerable distance and then the solution is allowed to flow very slowly through it into the bowel, the patient lying in the horizontal position, preferably upon the right side. The anal opening should be closed around the catheter by digital compression, and it is not to be forgotten that the greatest care must be exercised to see that the water flows slowly. Should straining come on the flow must be stopped until the spasm of the bowel ceases, when it may be resumed.

#### TAPPING THE PERICARDIUM.

Mr. AUSTIN MELDON read a paper on this subject before the Section of Surgery of the Royal Academy of Medicine in Ireland, which is reported in the *British Medical Journal* of December 12, 1896. In 1663 Riolanus first proposed paracentesis pericardii. One hundred years later Senac stated that the operation was possible, and still later Van Swieten suggested a method of performing it. In 1819 Romero, of Barcelona, operated with perfect success. Jowett, of Nottingham, operated in 1827, and Schuh in 1839. At present just 100 cases had been recorded, and he believed that many more had occurred which had never been published. Out of all these cases, only once had the operation proved fatal. In this unsuccessful case the right ventricle was lacerated by the trocar. Some

others had died soon after the operation, but these were cases that were moribund at the time it was undertaken. The remainder, without exception, were relieved, and many of them cured. Under these circumstances it was clearly the duty of the surgeon, whenever death was imminent from cardiac pressure, to resort to tapping. Experience, too, had shown that the operation is not attended with great danger, and certainly in cases of effusion from rheumatic pericarditis there was every prospect of recovery. He had seen several cases within the last thirty years in which he was convinced that the fatal termination was due to pressure of fluid in the pericardium, and might have been averted by drawing off the fluid. On one occasion he was able to verify this opinion by a post-mortem examination. He then gave details of two successful cases of tapping the pericardium. The first case occurred some years ago. The patient was a woman, aged fifty-eight, and seemed to be dying from increasing hydrops pericardii. The instrument he selected in this preantiseptic period was a long hydrocele trocar, which was washed well in very hot water. An incision was made into the skin two inches from the sternum in the fifth intercostal space, and in order to make it valve-like, the skin was drawn up to the full extent possible before making it. A trocar was with some difficulty inserted, and on withdrawing it fluid of a dark color followed. When eight ounces had been withdrawn the fluid flowed very slowly; the instrument was therefore taken out, and the wound covered with flexible collodion. As the patient appeared faint, a little brandy and ammonia was administered. An hour later all difficulty of breathing had disappeared, but although the patient expressed herself completely relieved, a very slight cyanotic condition remained. On the following morning this was gone, and her pulse was strong and regular. She left the hospital five weeks later in perfect health. The second case was that of a man aged twenty-six, to whose bedside Mr. Meldon was summoned on March 5, 1894. He was suffering from rheumatic pericarditis, with great difficulty of breathing, precordial dulness was greatly increased, and cyanosis and epigastric distress to a considerable amount were also present. The pericardium was tapped, and almost immediately the patient's breathing improved to such an extent that when  $5\frac{1}{2}$  ounces had been removed the needle was withdrawn. Cyanosis, dyspnea, and epigastric distress completely

disappeared in a few hours. The fluid, unlike that in his previous case, was a healthy serum. On August 31, 1894, a case occurred in the practice of Dr. Joseph Redmond in which 22½ ounces of dark-colored fluid were removed, and seven days later 27½ ounces were also taken out. In this case, which recovered perfectly, a drainage tube was subsequently inserted. Dr. Patrick Hayes was the surgeon who operated. The statistics of paracentesis pericardii showed that the fifth left intercostal space, at a point one inch to the left of the sternum, was the most suitable place for puncture. The selection of the instrument would likewise seem of some importance. If too small a cannula were used it was apt to become plugged with flakes of lymph. Mr. Meldon showed two instruments which had been made for him by Messrs. Smith & Sheppard. One was to be used with and the other without an aspirator. Both became arrested when two inches of the instrument had passed into tissues, and then any further depth was obtained by a screw motion. This latter is the suggestion of Dr. Woods. The author believed that when there was any fluid in the pericardium it was quite safe to plunge the trocar in fully two inches. He concluded by quoting Dr. Samuel West's conclusions to his able article in the *Medico-Chirurgical Transactions*, and which he believed should be adopted by the profession.

In the discussion which followed the PRESIDENT said the principal questions for consideration were as to the place where the puncture should be made, and as to the best way of dealing with the conditions that occurred when the disease became purulent.

Mr. LENTAIGNE said the operation was comparatively easy, and the results were likely to be satisfactory. In two cases which came under his notice not long ago the operation, which would very probably have given relief, was not permitted. Both patients were consequently allowed to die from what he might call simple heart suffocation, resulting from extreme distention of the pericardium.

Dr. FRASER recalled a case of pericardial effusion in which after death a measured gallon of fluid was drawn off. That case might have been beneficially treated by operation. He had, however, had fair success in treating pericardial effusion in rheumatic cases medically. He did not know what would be the use of tapping in the case of a "pineapple" heart surrounded with three inches of lymph. Again, there was a class of cases of rheumatic fever in which pericarditis

occurred, followed by delirium, and in which the effusion was not at all in proportion to the severity of the cardiac symptoms.

Sir THORNLEY STOKER said the great crux was how the case was to be dealt with when there was pus in the sac. When there was only serum, after it had been removed a reactionary condition was set up, and no further accumulation of serum occurred. But where there was pus, although the heart was relieved by the removal of it, a secretion of pus would continue where there were ulcerated or diseased surfaces; and the removal of it in the first instance was almost useless, unless means for subsequent drainage were provided. He thought the introduction of a trocar and cannula to such a depth as two inches unnecessary, except in the case of a patient of exceptional obesity.

Professor BENNETT gave particulars of a case in which, very early in his experience as a hospital surgeon, he was asked to tap the pericardium of a patient. He was unable to satisfy himself that there was fluid in the pericardium. As the man was in great distress he opened first the basilic vein on one side, and then that on the other. After there had been a full flow of blood from the second opening the symptoms were relieved. The man fell asleep, and the cyanosis entirely disappeared. After three or four days the man had a second attack of the same kind. He was not in attendance at the time, and in two or three hours the man died. He made a post-mortem examination, which disclosed an adherent pericardium and huge heart; and there was no doubt that if he had tapped him with a trocar and cannula he would have killed him on the spot.

Mr. WHEELER said he had had experience in two cases. In one three separate tapping operations were performed, fluid coming each time, and on the third tapping there was pus. The form of operation adopted was to dilate an opening with a forceps, pass in a cannula, and pass through it a very fine probe. The patient made a rapid recovery, was well in three months, and was perhaps alive now. In the other case tapping was performed once with an aspirator. The patient got quite well.

Mr. TOBIN said the difficulty as to depth might be met by using an aspirator and needle; and as soon as the needle was inside the skin the aspirator should be turned on. The moment the needle entered the pericardium the flow of fluid would show that it need be pressed no further.

Sir WILLIAM STOKES said it had never fallen to his lot to perform this operation, but it struck him as somewhat remarkable that in the cases mentioned by Mr. Meldon a single tapping should have been sufficient. In many cases it was sufficient; but they knew that cases of serous effusion occurred in which frequent tapping was necessary.

Mr. HEUSTON said when they were sure that there was only serous effusion they would be justified in using the trocar or aspirator in such a way as Mr. Meldon had adopted with such excellent results. But there were other cases in which the only proper thing for the operator to do was to make a free opening down to the pericardium, so as to be able to see what he was doing. In suppurative pericarditis it was absolutely necessary to make an incision at an early stage.

Mr. MELDON, in reply, said the position of the patient was of great importance in determining the depth to which the instrument should be inserted. In doubtful cases he would follow Mr. Tobin's suggestion. Selecting a No. 1 needle, and having created a vacuum in the aspirator, the instrument should be pushed in until the eye is covered, and the stop-cock then turned on. The needle might now be pushed in to a reasonable distance in search of fluid. Even should the heart be touched by such a small instrument, it would not be so very serious as has been stated, especially as the left ventricle has been designedly punctured, and the patient relieved by the operation. He was not aware of any case of rheumatic pericarditis in which a second tapping was required. The patient in the second case was kept in hospital for five weeks after the operation, because it was thought that all the fluid had not been drained off, but it never collected afterwards. As to a second tapping being more dangerous than the first, he had never tapped a second time, so that he could not say whether it was or not. Statistics did not show it to be so. There were two special points in reference to the signs of pericardial effusion to which he would draw attention. The first manifestation was increased broadening of the cardiac dulness at the lower portion, first to the left and then to the right, until there was absolute dulness in the fifth intercostal space in the region named by Ebstein—the cardiac hepatic angle. The second symptom was the occurrence of intermission of the pulse during inspiration at a time when the heart is beating without such intermission. Most of the other observations

had reference to purulent pericarditis, which was not treated of in this paper, but he quite agreed with the opinions expressed that this condition was best treated by incision and drainage.

**TREATMENT OF EPITHELIOMA OF THE  
FACE BY THE APPLICATION OF  
METHYLENE BLUE AND  
CHROMIC ACID.**

According to the *Revue de Thérapeutique Médico-Chirurgicale* of December 1, 1896, DU CASTEL has reported very good results from the employment of these drugs for this condition, when extirpation of the part which is affected is impossible. The ulceration is first softened by means of the application of a poultice of potato containing corrosive sublimate in the proportion of 1:100. Loose, easily disconnected tissues are to be removed with the galvano-cautery, and after this has been done and the part has been thoroughly cocainized the following solution is employed by means of a wad of cotton and forceps:

- ℞ Methylene blue, 15 grains;  
Alcohol and glycerin, 75 minims.

The parts which are stained by the methylene blue are then touched with chromic acid solution and immediately afterwards the application of blue is repeated. Finally the part is dressed with compresses wet with sublimate. The applications are repeated at intervals of two or three days, and usually in a month cure, or at least much benefit, will be manifested.

Du Castel believes that the application of methylene blue constitutes an excellent method of treatment, and that it exercises an incontestably advantageous influence over superficial epitheliomas; in addition it is entirely inoffensive and harmless. Of course it does not compare in usefulness with operative procedures where they can be undertaken.

---

**THE TREATMENT OF SYPHILIS BY IN-  
TRAVENOUS INJECTIONS OF  
MERCURY.**

In the *British Medical Journal* of December 12, 1896, ERNEST LANE writes interestingly of the plan of treating syphilis by intravenous injections of mercurial solutions and tells us that it was originally suggested by Baccelli in 1893, and has since been carried on by many Continental surgeons: in Italy by Jemma, Colombini, Nieddu, Cam-

pana, and Bruni; in Germany by Görl, Neumann, and Lewin; in France by Abadie; and in Russia by Stoukovenkoff and Kusel.

Having charge of all the male wards at the only hospital in London devoted to the treatment of venereal diseases, the writer has had unusual opportunities of giving a fair and impartial trial to any novel method of treatment; and, with a view of estimating the value of this plan, he has systematically adopted it in every case of syphilis which has come under his care in the London Lock Hospital during the last nine months, and he states with conviction that he has formed a very favorable opinion as to its merits, and believes that, with certain reservations, it compares favorably with other methods of treatment, whether it be by inunction, by intramuscular injection, or by internal medication, its special feature being the rapidity with which patients can be brought under the influence of mercury.

The preparation he has utilized throughout has been cyanide of mercury in one-per-cent. solution, and the amount used at each injection was usually 20 minims, or about  $1\frac{1}{4}$  grammes, though in some of the more severe cases he commenced with double this dose for the first one or two injections. At first the injections were employed every other day, but after a short time he decided to introduce them daily. A loop of bandage is first tightly applied round the upper arm, and selection is made of the most prominent vein in the neighborhood of the elbow-joint; the skin in that region is rendered aseptic in the customary manner, and the needle is thrust into the vein, the syringe filled with the solution being attached to it; the bandage is then removed, and the syringe is emptied into the vein and then rapidly withdrawn; the finger is placed on the puncture for a few seconds, and the operation is complete.

As will be pointed out later, when dealing with the advantages of this system, it is absolutely painless, and with ordinary precautions perfectly devoid of danger.

The number of cases treated amounted to seventy-six, and the number of injections made was upwards of one thousand. These injections were carried out by the writer's house surgeons (Dr. Byles and Mr. Chopings). The cases treated covered a very wide field, and embraced nearly all the possible manifestations of the disease, from the simple and uncomplicated case to severe tertiary ulcerative lesions of skin and mucous membranes, malignant syphilis, condylomata,

iritis, and chronic and relapsing syphilides. The number of injections necessary varied from forty-six to four.

As a result of the treatment fifty patients were relieved, and by relieved is meant that they left the hospital absolutely free from syphilitic manifestations; sixteen improved under treatment, but still presented some traces of disease on their departure; four either refused to undergo the treatment, or had to be discharged from the hospital for misconduct; and in six instances the treatment had to be suspended owing to the impossibility of bringing the veins into sufficient prominence to allow of the injections entering them with any certainty, but in several of these cases great improvement was noted before the treatment was discontinued. It is a perfectly easy matter to determine if the injection has missed the vein by the pain, swelling, and bruising which shortly supervene, whereas the injections if properly effected are followed by no discomfort of any kind; moreover, the sensation produced by the needle moving freely within the lumen of the vein differs widely from that which is imparted should it only have entered the cellular tissue. As a rule very little inconvenience was experienced by these patients in whom the injections missed the vein, but in a case in which the injections were made into the dorsal veins of the foot, which were somewhat varicose, a skin slough shortly supervened, leaving an ulcer which resisted treatment for some time. The vein usually selected was the median basilic, and no appreciable change could be detected in its walls, though in one case as many as twenty-three injections were introduced into each arm. As previously stated, the patients submitted to this treatment were all males, and it is hardly necessary to point out that, in dealing with women, greater difficulties would be encountered owing to the smaller size of their veins.

All the patients under the writer's treatment were admitted into the wards of the hospital; still he sees no objection to the treatment being carried out in the out-patient departments. There was no selection of suitable cases, but every syphilitic patient who presented himself was submitted to the intravenous injections, whatever his bodily state, and a considerable proportion had resisted previous treatment in the out-patient department, and were transferred to the wards of the hospital in consequence; many of them were in a most unfavorable condition, being

broken down by exposure, intemperance, and privations; nor were the patients very amenable to hospital discipline, and several of them left while still manifesting active signs of disease, whilst others had to be dismissed owing to breaches of regulations. In every case the diagnosis was made absolutely certain by the appearance of some secondary manifestation, and the treatment was never commenced until the nature of the case was satisfactorily proved. In a few cases diarrhea supervened during the treatment, but these attacks were transitory, and were possibly due to other causes; in some instances gingivitis occurred, but it was not so marked as after other methods of mercurial administration, and in no case was salivation noticed; the hygiene of the mouth was carefully attended to, and alum gargles were employed two or three times a day. In a few instances polyuria and very slight albuminuria were observed after the first or second injections, but these soon disappeared and did not necessitate any modification in the treatment. The only other remarkable feature to be recorded is that many of the patients experienced a metallic taste in the mouth immediately after receiving the first few injections.

The advantages of intravenous injections may be summarized as follows: They are absolutely painless, in which respect they are in direct contrast with intramuscular injections; the functions of the digestive tract are not interfered with; the doses of the mercurial salt are small, are certain of absorption, and can be easily regulated to the varying susceptibilities of different individuals; with ordinary precautions the treatment is perfectly safe, and even if the vein is missed little or no inconvenience is caused thereby; the resulting improvement is certain and rapid, and consequently it would seem to be indicated in cases of cerebral syphilis. His experience does not warrant him, he states, in offering an opinion as to whether this treatment is followed by relapses, but so far he has not met with any. The only real objection is the difficulty experienced in some instances of bringing the veins into sufficient prominence, and in a certain proportion of cases, especially among women, this is an insuperable obstacle. In conclusion, he is of opinion that in intravenous injections we have a valuable addition to our antisymphilitic therapeutic agents, though the plan is one which obviously cannot be recommended as a routine in practice.

#### OPERATION AND CURE OF A CASE OF ADDISON'S DISEASE.

A malignant retro-peritoneal tumor was diagnosed in the case of a woman presenting all the symptoms of Addison's disease. When removed it was found to be a suprarenal capsule in a state of tuberculous degeneration. All the various symptoms disappeared completely after the operation, and the patient has enjoyed good health ever since. There were no organic lesions except this tumor and an old tuberculous focus in the lung. It must be evident, therefore, that the condition of the capsule was responsible for the development of the disease; hence the removal of one or both capsules in Addison's disease seems to be indicated. The operation is not difficult, as a tubercular capsule is more easily separated from neighboring organs than a sound one.—*Zeitschrift für Klinische Medizin*, No. 2; *Journal of American Medical Association*, Dec. 26, 1896.

#### CAUSE AND PREVENTION OF SUPPURATION OF STITCHES.

Some recent writers attribute the occasional suppuration of the stitches in carefully performed operations to the presence normally of certain pathogenic micro-organisms in the underlying layers of the derma, which cause suppuration when exposed to the air by the wound. REMLINGER even asserts that most of the micro-organisms found in the blood drawn from the finger are derived from the lower layers of the skin. His statements are revolutionary in regard to the conclusions we have been drawing from inspection of a single drop of blood in infective disease. We know that the flora of the superficial layers is extensive, but he announces that he found the *staphylococcus albus* (twenty-three times), *aureus* (eleven times), and *citreus* (fourteen times), the *streptococcus pyogenes* (eight times), and the *coli bacillus* (five times), in his experiments on fifty perfectly healthy men, taken with a sterilized needle from the deeper layers of the derma. The only means to avoid error in examining the blood is to draw it from the deeper tissues with a needle not only sterilized but inserted while still red-hot. The logical inference is that surgeons should make their incisions with the thermocautery in order to destroy these intracutaneous germs, but the same effect is secured by a much simpler method, the disinfection of each stitch with alcohol, as E. Blondel announces in the *Journal de Médecine de Paris*.

in an able review of the subject and the latest theories. He has revived the Hippocratic practice of bathing wounds with wine, as taught by Theodoric and Mondeville, and applies it with invariable success. Especially in total perineorrhaphy, which is so difficult to perform with perfect antiseptis, he has secured results far surpassing any previous achievements. He makes as few stitches as possible in the lower layers, and before drawing them tight he wets them and the edges of the wound with ninety-per-cent. alcohol, and sponges the tissues with a cotton pad dipped in it. Each suture is treated in the same way, and the final suture is sponged with strong alcohol and then dusted with iodoform or equal parts of dermatol and aristol, repeated every second day afterward. Alcohol dries the surfaces better than any other substance; its effect on grease is also a factor in the result, and it has a coagulating effect on the serum and thus favors cicatrization.—*Journal of the American Medical Association*, Jan. 30, 1897.

#### INDICATION FOR THE USE OF THYROID EXTRACT IN GYNECOLOGY AND OBSTETRICS.

CHERON (*Revue Médico-Chirurgicale des Maladies des Femmes*, November 25 and December 25, 1896) holds that thyroid extract is an excellent remedy in threatened abortion with hemorrhage, and is valuable in preventing the arrest of uterine involution after childbirth, and that it is potent against the premature return of the monthly periods. Moreover, it is a valuable galactagogue.

Thyroid extract in other words stimulates the mammary secretion, whilst it lessens functional activity of the uterus. In gynecology it has proven valuable in the control of all forms of uterine hemorrhage, whether this be due to endometritis, tumor, or lesions of the adnexa.

The contraindications to the employment of the drug are: tuberculosis, since this seems to be stimulated rather than arrested. In heart disease, even though thyroïdin is strongly indicated, it should be administered with the utmost care and should be stopped at once upon the first suggestion of tachycardia. Symptoms of thyroid intoxication are tachycardia, oppression, exophthalmos, and irritability. In certain cases the drug produces rapid emaciation. Sometimes gastric vertigo has been observed. Because of the difficulty experienced in procuring the fresh

gland and the repugnance which patients exhibit in consuming it, it is well to administer it in the dry form prepared by druggists—this may be obtained in tablets, pastilles or capsules—in doses of  $1\frac{1}{2}$  grains twice daily before meals. After a month there should be an interval of eight days during which the drug is discontinued, followed by a three weeks' course of the medicine. If indications still exist for its employment a rest of two weeks is given, followed by two weeks of the drug.

#### ALEXANDROFF'S SIGN FOR EARLY DIAGNOSIS OF COXALGIA.

Beside the usual symptoms of incipient coxalgia, ALEXANDROFF (*Presse Médicale*, Dec. 9, 1896) insists on the importance of two additional signs, the atrophy and fatty degeneration of the muscles and bones, and especially the hypertrophy of the subcutaneous cellulose-adipose layer, which exists in every stage of the disease from the first and increases with the gravity of the case. In advanced stages the hypertrophy extends throughout the whole member. This is the cause of the effacement of the fold between the thigh and buttocks (*pli fessier*), and the difference in this respect between the sound and the affected thigh is very evident—as much as one and a half to four millimeters in some cases. Alexandroff has invented a special instrument, the adipometer, resembling Weber's compass, to measure the thickness of this subcutaneous layer. The movable portion of the apparatus slides on a graduated plate and a spring near the handle allows a pressure of five to ten grammes. He has been using it for six years and states that atrophy of the member coinciding with hypertrophy of the fold is one of the most important signs by which to recognize tuberculous osteoarthritis before any other symptoms have appeared, while the absence of these trophic troubles is conclusive evidence of the non-existence of a tuberculous lesion of the coxo-femoral articulation, even when it is indicated by other symptoms.—*Journal of the American Medical Association*, Jan. 30, 1897.

#### ABSCCESS OF THE LUNG.

W. P. NORTHRUP (*New York Medical Journal*, Jan. 16, 1897) reports a case of abscess of the lung in which operation was attended by prompt recovery. The patient was an English woman, aged twenty-three, waitress.

On admission to the surgical division on September 26, 1895, her temperature was 104°, pulse 125, respiration 32; there was extreme dyspnea, and the heart's action was very feeble. Physical examination of the left lung was negative. Of the right: behind, râles over two-thirds, indifferent in quality, occasional; slight dulness over lower two-thirds, vesicular breathing heard close under the ear, no bronchial element to voice or breathing. Nothing heard over the posterior or post-lateral aspects to give any clue to the diagnosis; certainly could not suggest a source from which such a quantity of expectoration could come as the patient brought up. Anteriorly at apex there were exaggerated pulmonary resonance and respiratory sounds. All positive physical signs were from the third space downward; over this there was flatness, continuous with the liver to the free border of the ribs. The level of flatness gave the impression of a liver crowded up to the third space. The line of flatness was straight and sharp from the sternum to the anterior axillary line; here it became indistinct, apparently dipping deeply inward and turning downward to the liver flatness. It was as though a quart water-bag had been shoved in from under the sternum, crowding the lung upward, backward, and toward the axillary line. Over this area there was flatness continuous, absence of all respiratory sounds, no bronchial voice, and there were no râles or friction sounds; it suggested the signs one gets where sarcoma has produced a solid tumor in the mediastinum or root of the lungs. The heart was not crowded from its normal position, nor was the liver displaced downward.

The question which first presented was whether this was encapsulated empyema emptying itself through the bronchial ways, or abscess in the lung. It was at first thought to be probably the former, but when it came to exploratory puncture the opinions had rather turned to the second. Incidentally the site and manner of puncture indicated the diagnosis entertained.

The patient was assisted to sit up in bed, the right forearm bent over the top of the head. A long, large-calibre exploring needle on a piston syringe was used. The needle entered at a point just posterior to the breast, about the anterior axillary line, on a level with the third space (at sternum). It was then directed, not toward the superficial flat area, but deep, and as near as possible toward the root of the lung, and thrust in up

to its limit before drawing the piston. When the air was exhausted the barrel promptly filled with thick, stinking pus.

This did not of course distinguish between an encapsulated empyema lying in the position of the water-bag—that is, touching the chest-wall in front and extending deep along the mediastinum and in the direction of the root. The sputum was examined repeatedly for tubercle bacilli and actinomycosis rays without success. The nature of the process was never determined by exact test.

The diagnosis was deep-seated pus in the right lung, either encapsulated interlobar empyema or pulmonary abscess near the root.

Operation was performed under ether anesthesia. Several exploratory punctures were made with a large needle below and to the outer side of the right breast, but no pus was found. An incision two inches long was then made over the sixth rib, below and just external to the right breast in the anterior axillary line. A portion of the rib an inch and a half in length was excised and an entrance thus gained into the pleural cavity, which was found free from fluid of any kind. This exposed the vault of the diaphragm, and superior to this, but not in contact with it, was felt the lung, consolidated, contracted, and occupying the upper and inner half of the right thoracic cavity. The incision was carried upward and backward along the rib into the axilla and an additional two inches of rib excised. The finger was then swept around the lung, which was seen and felt to be firmly adherent to the superior internal and anterior wall of the right chest. Except at the apex, however, there were no adhesions toward the external wall, and the contracted lung was at least two inches distant from that part of the chest-wall where the incision had been made. A large exploring needle was plunged directly into the centre of the lung, and at the depth of two inches pus appeared in the syringe. The needle was left *in situ*, and along it an incision was made by scissors through the consolidated lung tissue until the abscess cavity was reached, when about three ounces of thick and very fetid pus escaped. The cavity was freely opened, and the finger passing into it broke up a number of trabeculae and pulled out a long strip of sloughing tissue with a very foul odor. A soft spot being felt in the internal wall of the abscess, the scissors, guided by the finger, was plunged into this and entered another cavity from which there

was an escape of an ounce of pus of a similar character. This cavity was also freely opened, and all bands of tissue broken up by the finger. The hemorrhage from the incisions in the lung was insignificant and needed no mechanical procedures for its arrest. The cavities were rubbed, and all loose and broken-down tissue was swabbed away with gauze sponges. No irrigation was employed; strips of iodoform gauze were packed into the cavities alongside of two soft-rubber drainage tubes. The ends of the strips and tubes were brought out through the opening in the chest-wall and a copious sterile dressing applied. Severe shock followed, and for several weeks the patient remained in a very critical condition.

During December the gain was very rapid; by the 20th the cough had almost disappeared, as had the expectoration. The lung was slowly expanding. The opening into the chest was completely closed. The patient's general condition was so good that she was allowed to return to her home, where she has continued to gain flesh and strength.

#### TECHNIQUE OF CÆSAREAN SECTION.

B. C. HIRST (*American Journal of Obstetrics*, January, 1897) calls attention to the fact that operations of tracheotomy and herniotomy may be forced on the general practitioner in an emergency at any moment. But the exigency requiring a Cæsarean section will be rare, occurring only once perhaps in the course of a general practitioner's career. From a personal experience, unusually large in America, of fourteen Cæsarean sections, in which he has tested every method proposed by modern operators, he has settled down in the past three years to a technique which has proved so satisfactory in the operation itself and in its results that the writer intends clinging to it indefinitely.

If there is time to make the best arrangements the Cæsarean section should be performed at a convenient hour of an appointed day, like any other abdominal section. A period about two weeks or ten days before term should be selected. It is unnecessary to excite labor pains beforehand or to secure any degree of dilatation of the os. The preparation of the patient herself is like that for any abdominal section.

The patient on admission is given a full hot bath. Have her kept in bed from the time she enters the hospital until the operation is performed. Administer pill: strych-

nine  $\frac{1}{4}$  grain, digitalis  $\frac{3}{8}$  grain, quinine 2 grains; three times daily before operation. Secure movements of bowels by two drachms Rochelle salts every evening. Have the heart and lungs examined, and also the urine.

The diet before operation consists of gruel for breakfast, soup for dinner, milk-toast for supper, one glass of milk at 10 A.M., 4 P.M., 9 P.M.

As to medicine, at 5 P.M. the day before operation, ten grains sulphonal in half a glass of boiling water, cooled down to temperature that permits patient to drink it, if patient is nervous and has been sleepless; 9 P.M., half-ounce of Epsom salt in a tumblerful of water.

Evening before operation, first cleansing of the abdomen, as follows:

1. Sterilize the following articles for twenty minutes at 240°: soft bristle-brush; absorbent cotton; one-half dozen towels; gauze, unmedicated; binder; long gown.

2. The resident physician, or, under his supervision, the nurse who cleanses the abdomen, must prepare his or her hands and arms as though about to operate, namely: remove rings; scrub with brush, hot water, and tincture of green soap for ten minutes; clean nails with nail-file; scrub hands and arms with benzine and then with alcohol; immerse hands and arms in bichloride solution (1:1000) for two minutes. Then put on the gown.

3. The abdomen, from ensiform to symphysis and from flank to flank, must be thoroughly scrubbed with soft bristle-brush, tincture of green soap, and hot water (for at least ten minutes), paying special attention to navel and to pubic regions. Wipe off the razor with cotton and alcohol; shave pubis, then scrub thoroughly with alcohol. Cover the abdomen with the sterile gauze, and put on the binder.

On the morning of operation give a cup of beef-tea at 7 A.M. The hands of the nurse and doctor should be cleansed as described above; articles resterilized as described above; same cleansing of abdomen repeated as above, but in addition, before alcohol scrubbing, scrub abdomen with benzine; wring out a sterile towel in 1:1000 bichloride solution and cover the abdomen with the towel; put over it a thick layer of sterile cotton; apply binder. Catheterize the woman just before anesthetization with sterile glass catheter in aseptic manner. Give vaginal douche, one quart of 1:4000 solution, followed by a little sterile water. If bowels have not

opened freely give enema—a pint of soap-suds and one drachm of turpentine.

With a large scalpel held firmly in the full hand a free incision is made from two inches above the umbilicus to just above the symphysis. This incision may be carried entirely through the abdominal wall in its upper part—the intestines are out of the way. The abdominal opening is enlarged with scissors downward as low as possible. An assistant makes the wound gape while the operator delivers the womb from the abdominal cavity. The assistant then approximates the edges of the abdominal wound as closely as possible around and above the cervix, at the same time squeezing the latter with his outspread hands. With a few rapid but light strokes of the knife the operator makes an incision an inch in length through the uterine muscle, but not through the membranes, so as not to cut the child. Then with one rapid movement of the left hand and arm the uterine wall is torn down to the internal os, the membranes are ruptured, and the placenta, if in the way, is detached and pushed aside; the child is seized by the most accessible part—shoulder or leg—is delivered, and, with placenta still attached to it, is dropped into a sterile sheet spread out over the outstretched arms of an assistant who stands directly at the operator's left hand, and whose duty it is to revive the child, if asphyxiated, and to tie and cut the cord. Up to this point the operation rarely requires seventy-five seconds. Then follows an easy hysterectomy: ligation of the ovarian arteries and of the arteries of the round ligaments, application of clamps, cutting of the broad ligaments, preparation of peritoneal flaps, amputation of the womb, ligation of the uterine arteries, and oversewing of the stump, which is dropped.

The abdominal wall may be closed by close-set interrupted stitches—the easiest plan for a beginner—or by any other method that a more experienced operator may prefer.

#### ANTITOXIN, INTUBATION, AND TRACHEOTOMY.

DOUGLAS in the *Archives of Pediatrics* for February, 1897, reports an interesting case occurring in his practice in which he employed successfully antitoxin, intubation, and tracheotomy.

In young children suffering from diphtheritic laryngitis, with partial stenosis, where the necessity for quick relief demands the prompt use of antitoxin, we are confronted

occasionally with a sudden increase of the dyspnea due either to a rapid loosening of the membrane, causing occlusion of the narrow opening in the larynx, or perhaps due to that first change or swelling of the membrane caused by the antitoxin. In these cases the immediate necessity for relief either by intubation or tracheotomy becomes imperative.

In many cases during intubation, or rather the first efforts at inserting a tube in the larynx, we loosen the false membrane and thus cause a partial occlusion, or even a complete closure of the larynx. Where a patient is much enfeebled and has been suffering from dyspnea for many hours with well marked cyanosis, the introduction of a tube may endanger life, through thus suddenly loosening the membrane when he has not sufficient strength to expel it, or where the increased effort necessary to do this is more than the strength of the patient can accomplish. He rapidly becomes more cyanosed, breathes less frequently, and death seems certain within a few minutes. Here the physician dare not again insert a tube, and must resort to tracheotomy.

Such a train of symptoms occurred in a child of six years under the writer's care. It had suffered previously at four and five years of age with bronchopneumonia, the latter attack being in the spring and complicated with whooping-cough. This attack lasted two months, after which she made a good recovery, and at the invasion of diphtheria she was in apparent good health. The membrane covered the tonsils, both nares, the pharynx, and finally developed in the larynx. By this time antitoxin had been obtained and injections commenced. The first dose was given in the evening; dyspnea increased greatly during the night, and in the morning she had great recession in the chest-walls with marked cyanosis. Intubation was performed at once. After inserting the tube dyspnea was much increased, as also the cyanosis. This was ascribed to loosened membrane and obstruction of the tube. The tube was removed in a few minutes, but breathing became slower, reflex irritability ceased, and the patient was being rapidly asphyxiated. So far had the nerve centers become insensible that she lay perfectly quiet, recognizing no one; gasping slowly, and rapidly dying. A rapid tracheotomy was resorted to, when the patient immediately revived, and a good recovery resulted. Four injections of antitoxin were given, amounting in all to 3000 units.

A second case is related, a child of eleven years, suffering from laryngeal dyspnea of diphtheritic origin. Little membrane could be seen, but the distressing dyspnea, cyanosis and recession of the chest-walls demanded instrumental relief. Intubation failed. It is probable some of the membrane was dislodged and the glottis plugged with it, for the child did not breathe again; she became blue at once and after a few struggles lay as dead. Slapping the back and compressing the ribs failed to secure even one inspiration. The heart continued beating feebly. A rapid tracheotomy and artificial respiration were resorted to, the heart ceasing before their completion; the patient after two minutes began again to breathe under these measures and recovered. It was very interesting to note the immediate response of the heart to the first natural inspiration. While artificial respiration secured a rush of air through the tube and a partial filling of the lungs, no appreciable result was shown on the heart, and no pulse appeared till after the first natural inspiration. Antitoxin was used.

#### A NEW SIGN OF FECAL TUMOR.

GERSONY (*Wien. Klin. Woch.*, Oct. 1, 1896) describes a sign which, if detected, will often save a patient from needless laparotomy. He is not as yet certain how commonly it is to be met with in cases of fecal impaction. If the tumor be firmly pressed on with the finger the intestinal mucous membrane adheres to the sticky masses of which it is composed; when the pressure is removed the mucous membrane slowly disengages itself, and the sign consists in the recognition of this gradual separation. The only conditions necessary for its production are a certain degree of dryness of the intestinal mucous membrane and a certain impressibility of the fecal mass; the surface of the latter can be softened if necessary by an oil enema. The important factor is undoubtedly the pressure of the intestinal gases. The characteristic sensation can be obtained by pressing the oiled or soaped volar surface of one forefinger into the palm of the other hand and very slowly withdrawing it. Gersuny relates a case of an enormous fecal tumor in a woman of thirty-two; this sign was present, but as he did not at that time recognize its significance he opened the abdomen. He also records two cases occurring in Osler's practice, in which the detection of this sign not only saved the patients from operation, but also

indicated the correct line of treatment. All these three cases seem to belong to the same clinical group; the affection began in infancy with irregularity of the bowels and constipation, which remitted for a time under the influence of purgatives and irrigation, only to recur with increased intensity, till at last chronic intestinal obstruction resulted. With this was associated hypertrophy of the large intestine, which became longer, wider, and more thick-walled; the contraction of the walls offered at times an increased obstacle to the passage of feces. Patients suffering from this complex symptom are ill-developed, pale, and thin; purges, irrigation, and massage fail to affect the fecal tumors. The only means of removing these is the combination of oil enemata and massage, which reduce the intestinal contents to a pasty mass, which can then be expressed. The detection of Gersuny's sign, therefore, indicates this treatment.—*British Medical Journal*, Jan. 2, 1897.

#### RESECTION FOR DISEASE OF THE ANTERIOR LOBE OF THE BRAIN.

DURANTE (*Supplem. al Policlinico*, October 31, 1896) at the recent congress held in Rome reported the case of a man who had suffered for some time from pains in the head, which were at first lessened by antisymphilitic treatment. Later, prominence of the left frontoparietal region, exophthalmos, and amblyopia came on. The man's memory had diminished, and he became melancholy and unsociable; he also had hallucinations. A semicircular osteocutaneous flap was made, and the part trephined. Three hard syphilitic gummata were removed from the frontal lobe. Next day the man's vision returned, and eight days later the intellectual and moral faculties returned to their normal condition. The headache disappeared. Six months later he had an attack of Jacksonian epilepsy, probably due to post-operative meningo-encephalitis.

Another case was that of a woman previously shown at a congress held in Perugia, suffering from loss of memory of words and things, religious perversions, altered moral sense, etc. Upon operating a fibrous adherent body was found and removed. The patient changed as if by magic, and speedily recovered her intellectual and moral faculties, and left the hospital cured. Two months later slight epileptoid attacks occurred, probably due to slow inflammatory processes.

The author dwells on the advantages of an osteocutaneous flap in these cases. Maffucci

mentioned five cases confirming the view that the frontal lobe is the seat of ideation.—*British Medical Journal*, Jan. 2, 1897.

*A METHOD OF PREVENTING VAGINAL PROLAPSE FOLLOWING ABDOMINAL HYSTERECTOMY.*

J. M. BALDY presents an interesting paper with the above title in the *American Journal of Obstetrics* for January, 1897. He states that vaginal prolapse following hysterectomy has during the past few years been noted and reported in several instances, and it seems not improbable that such untoward sequences will be more and more frequently noted in the future, as the ultimate results of this operation as performed during the past few years are gradually gleaned. The fact that this complication is beginning to be observed is by no means surprising when the anatomical relations of the pelvis are noted and compared as they exist before and after the operation.

Dr. Baldy states that his procedure is in all essentials an abdominal hysterectomy by amputation at or below the internal os. The points to be observed are: to include both the ovarian arteries and the round ligament in the first ligature on each side of the uterus; to place this ligature as near the pelvic wall as possible, so as to leave but a small amount of broad ligament behind with the stump; to place but one other ligature on each side of the uterus, this ligature to include the uterine artery with as little other tissue as possible, which leaves both broad ligaments open; to amputate the uterus as low on the cervix as possible. The sutures employed are of heavy silk, which in the course of their application include both the ovarian and uterine stumps, deeply placed well back of the ligatures. These points are important, as considerable traction occurs when the sutures are tied, and unless these precautions were taken the suture might tear out or the ligatures on the stumps become displaced. The sutures include the sides of the cervical stump.

The effect of tying these sutures is to lift up the stump of the cervix together with the vagina and to bring it in close approximation with the ovarian stumps, doubling the opened broad ligaments together. Of course the portion of the broad ligament at the point of the ovarian stump will be drawn down somewhat, but the main effect is to lift to a high point the cervical stump and at the same

time to drag up the vagina. Adhesions take place throughout the full extent of the doubled broad ligament, and most surprisingly firm support is given from above to the vagina. The peritoneum is drawn together by a continuous catgut suture over that portion of the cervical stump which remains uncovered after the two sutures are tied.

The results accomplished by this operation are: The weight of the heavy uterus is removed; the overstretched vagina is lifted high up and held firmly in place; the supports utilized are the natural supports of the uterus and upper portion of the vagina—the broad ligaments; the cervix remains a pelvic organ; the immediate and remote result as regards fixation of the upper part of the vagina is perfect.

Where there is a cancerous or tubercular uterus to be considered the operation can readily be modified by completely removing the cervix and (after closing the vagina by a continued whipped suture of catgut in the mucous membrane) passing the suture through the vaginal vault instead of through the cervix.

Our aim in placing the sutures should be to open up as little of the broad ligament as possible; to have the vagina as high as possible after the uterus is removed; to place all possible obstacles in the way of vaginal sagging. This can be best accomplished by placing but four ligatures instead of six and making each ligature include as much tissue as is consistent with safety. The first ligature should pass through the broad ligament below the round ligament; it should include both the ovarian artery and the round ligament with its vessels. The ligature about the uterine artery should then include also as much broad-ligament tissue as possible; this can best and most safely be accomplished by tying the artery as it passes up along the side of the cervix, and not in the base of the broad ligament as is usually recommended. If the ligature be so placed there is absolutely no danger whatever of tying the ureter, provided of course there is no anomaly in this organ.

*THE TREATMENT OF WOUNDS BY GLUTOL (SCHLEICH).*

THOMALLA (*Therapeutische Monatshefte*, January, 1897) states that for many months he has used formalin-gelatin (glutol) as a surgical dressing applied to neatly apposed incisions which have been kept clean. The results are about the same as those noted

under other dressings—i.e., prompt primary healing. When used as a dressing to ragged and irregular wounds which cannot be neatly apposed, suppuration does not occur. Necrotic fragments quickly separate and cicatrization takes place more rapidly than under other dressings. When wounds are suppurating and are not thoroughly drained the use of glutol is not satisfactory, since a scab quickly forms beneath which pus collects. It is well under such circumstances to remove a part or the whole of the crust and again apply glutol to the wound surfaces. In this way suppuration is quickly limited and the healing is prompt. It is not necessary to remove the entire crust, but only a sufficient portion to allow the free escape of the retained secretion.

Glutol is especially serviceable in the treatment of burns. Originally Thomalla removed the scabs, but as suppuration never took place he allowed them to remain, and has never had infection, excepting in one case, the wound cicatrizing rapidly. This one case was a burn of the foot which was prevented from healing by the rubbing of the shoe. His reason for letting a scab form and remain for several days in the treatment of burns is based on the fact that when suppuration does not take place a breaking up of the glutol and a setting free of the formalin is not required, while the scab acts as an excellent protective to the surface below. Glutol is also advised in all those small wounds which cannot be conveniently bandaged—for instance, such as are inflicted on the fingers and hands of workmen who continue their occupation. Glutol is sprinkled on the wound and over this is painted collodion. On the collodion is sprinkled another layer of glutol, thus forming a water-tight scab. In no instance was there suppuration or growth of proud flesh. The author holds that glutol is the best antiseptic which the surgeon can use in the form of powder, and that it has an extremely wide range of application.

#### NEW DRESSING FOR CIRCUMCISION.

After the operation clean the penis with some aseptic solution, then paint the penis from the meatus to the root with the following:

- Resin, 1 drachm;
- Copal varnish, 1 drachm;
- Beeswax, 1 ounce;
- Tallow, 2 ounces;
- Iodoform, 1 drachm.

—*Indian Med.-Chir. Review*, vol. ii, No. 5.

#### EXTRA-GENITAL CHANCROID.

KREFTING (*Norsk Magazin for Laegeviden-kaden*, 1896) records seven cases of extra-genital chancroid. These cases were due to autoinoculation from a genital ulcer, and were situated over the perineum, the back of the hand, right thumb, right side of the breast, the left middle finger, and the left forearm. Diagnosis was confirmed by microscopic examination. The seventh patient exhibited only a soft chancre on the right index and had no history of venereal ulcer. Diagnosis was confirmed by autoinoculation and finding the microbe.

Fournier states that soft chancre of the head is moderate in extent, superficial, solitary, and quickly heals. Diagnosis can be made only by autoinoculation. The treatment is thus appropriate to genital chancroid. —*Monatshefte für Praktische Dermatologie*, bd. xxiv, No. 1.

#### ROENTGEN RAYS USED FOR DETECTING BULLETS IN THE HEAD.

SCHIER (*Wien. Med. Presse*, 1896, No. 33) reports the case of a patient who five years ago was shot in the right brow. The symptoms suggested that the ball was lodged in the ethmoid bone. There was complete palsy of the right trigeminus, with the exception of the motor filaments, loss of taste in the anterior two-thirds of the side of the tongue, palsy of the right olfactory nerve and the right optic. It is supposed that besides the direct wound there was a fracture of the base, thus accounting for the palsy. The Roentgen-ray picture, taken from different directions, showed that the bullet was located near the petrous portion of the right temporal bone, near the Gasserian ganglion.

#### THE USE OF AMYLIFORM IN SURGERY.

CLASSEN (*Therapeutische Monatshefte*, January, 1897) holds that amyli-form is a true chemical combination of starch and formaldehyde, proving this on apparently incontrovertible grounds. He claims for this preparation that it is absolutely free from irritating properties, and non-toxic, that it favorably affects the secretion and prevents tissue necrosis, that it does not form a dry crust which retains secretion, and that it will absolutely prevent the foul odor from gangrenous wounds.

Langaard holds that amyli-form is greatly to be preferred to this drug.

### BACTERIAL THERAPY OF MALIGNANT GROWTHS.

PETERSON (*Therapeutische Monatshefte*, January, 1897), after a review of the literature bearing upon the bacterial therapy of malignant growths, states that cases treated in Czerny's clinic warrant the following conclusions:

The treatment is absolutely worthless as applied to carcinomas.

Very exceptionally sarcomas apparently disappear.

The treatment itself is dangerous.

### TREATMENT OF TRAUMATIC TETANUS WITH CHLORAL HYDRATE AND BROMIDE OF POTASSIUM.

BHICCAJI (*Indian Medico-Chirurgical Review*, vol. ii, No. 5) reports the case of a female Hindoo applying for treatment for the lobule of her left ear, which was torn through. The injury occurred on February 20. On February 24 about midnight the reporter was called to see her at her house, where he found tetanus had appeared. The woman was removed to a hospital and the wound of lobule of ear antiseptically dressed. He prescribed fifteen grains of hydrate of chloral, with equal weight of bromide of potassium, every four hours. On the third day the patient was much better. Treatment was continued for eight days and the patient discharged cured on the fifteenth day.

### THE TREATMENT OF COMPOUND FRACTURES OF THE CRANIUM.

In the *Lehigh Valley Medical Magazine* for December, 1896, appears a valuable *résumé* of the treatment of complicated fractures of the cranium, contributed by W. L. ESTES.

The treatment of severe injuries should be upon the same principles as complicated fractures elsewhere. The cranial cavity is no longer the *noli me tangere* of surgery. With asepsis and thorough drainage, results which formerly were considered quite impossible are now being obtained by every modern surgeon. Unless the surgeon is prepared to do any necessary operation, including cleansing, disinfection, removal of offending pieces of bone, suturing the dura, etc.—after evacuating lacerated and detached cerebral tissue—he should confine himself to attempts to control hemorrhage and prevent further soiling of the wound. When he renders first aid, the wound should never be explored fur-

ther than to separate the hair, and by means of the hair the lips of the wound, very gently and carefully, in order to discover the extent of the injury. Soiled fingers poked into a cranial wound have many a time signed the death-warrant of the injured person, and the knowledge gained by touch has rarely been of any service in the immediate handling of the case. If there is free hemorrhage it ought to be checked. There are two possible sources of this hemorrhage: the vessels of the scalp and the intra-cranial vessels. Exploration of the wound at this time should be only to find out whether the bleeding is from the scalp or from within the cranium. Usually scalp hemorrhage may be controlled by placing a thin compress under the surface of the wounded scalp and another above the surface, and by a bandage gently squeeze the edges of the scalp between the two. The hands should be carefully washed before doing this manipulation, and only the least possible manipulation be employed—in other words, the condition of the wound should be disturbed as little as possible. The compresses should also be perfectly clean—if practicable, sterile. Unless means be at hand for thoroughly cleansing the wound and its surroundings, it is best not to attempt it at all. If the hemorrhage is from the inside of the cranium, or from the diploe, packing must be used, if the bleeding is at all severe. Pack the crevices between the fragments of the bone with some clean, thin fabric (gauze is best if it can be obtained), and then fill the whole wound tightly with the same material and bandage firmly in place. Then the patient should be transported to a place where he will receive permanent care and attention as soon as possible; and his head should be kept a little elevated during the journey.

These injuries always require an operation. Frequently the operation will be only raising a little depressed bone and suturing the scalp after most careful cleansing; occasionally, however, it will be necessary to remove a quantity of comminuted bone, clear out a quantity of lacerated cerebral tissue, stop profuse hemorrhage, attempt to restore or replace lacerated dura, provide for deep drainage, do some heteroplastic operation to prevent a subsequent hernia of the brain, and transplant the scalp to cover the opening in the bones.

When the surgeon is ready for the permanent dressing and operation, the first act, after getting the patient in a suitable light

upon a proper table, should be to clip with a scissors or hair-clipper the hair about the wound, and then from the wound outwards over the whole scalp, or over so much of the scalp as to insure absolute safety from any infection from the hair. During this clipping the wound should be covered by a piece of sterile gauze. Now the immediate surroundings of the wound for some distance about it should be shaved after careful lathering with green soap. Care should be taken to shave in a direction away from the wound, and while wielding the razor the flaps of the scalp should be steadied by gentle pressure. The patient may now be chloroformed. (He thinks if there is no organic heart lesion chloroform is better than ether in these cases.) Even if he be seemingly unconscious he is apt to have so much reflex left that manipulations will produce struggling. When under the anesthetic, have an assistant carefully douche the wound with a warm, sterile normal salt solution, and thus wash away detritus, clots, hair, and dirt from the wound itself and its immediate surroundings. During this time the operator and his chief assistant should thoroughly scrub and sterilize their hands. The first assistant, after irrigating the wound and surroundings, should place over it sterile gauze and carefully hold it in place while he washes with green soap and water the whole scalp, then use ether and alcohol to remove sebaceous matter, scales, etc., and then a warm five-per-cent. solution of carbolic acid, and lastly the sterile salt solution. Place the head on a firm, sterile, rubber-covered pillow, and now again irrigate the wound carefully with the sterile, warm salt solution. The surgeon may now begin his exploration and operation. The instruments, of course, should have been thoroughly sterilized, and they should be kept in a warm solution of carbonate of sodium during the operation. The author's experience suggests the "bull" that in "trephining" for depressed compound comminuted fractures never use a trephine; the instruments usually necessary are a knife, a pair of blunt-pointed scissors, a chisel, a good, sharp, strong Hopkins rongeur, two or three bone forceps with different curves, an elevatorium, two thumb forceps (one rat-toothed), a half-dozen hemostatic forceps, small and medium sized curved needles and a good needle holder, small and medium silk, silkgut and catgut for sutures and ligatures. The small needles should be previously threaded and ready for instant use.

The operation is begun by incising the scalp over an area sufficient to expose freely the depressed bone, following the line of laceration as far as practicable; rapidly raise and separate the scalp and pericranium from the bones, catch every bleeding vessel in the scalp, turn back the flaps, chisel or gouge the edge of the peripheral fixed bone to get under the edge of the depression with an elevatorium or bone forceps; the depressed bone should be slowly and carefully lifted up. If the fragments have been much soiled, as they frequently are, they should be removed entirely; if not at all soiled the question of their removal will depend upon the condition of the fracture; if very much comminuted and displaced, and the dura and cerebral tissues much damaged, they should as a rule be entirely removed and kept in a warm sterile saline solution with the idea that in certain cases they may possibly be replaced. With the removal of the depressed bone hemorrhage will occur if any principal vessel is involved; this sometimes is a most formidable complication when a sinus is injured or the middle meningeal artery is torn low down. As soon as the bone is out and hemorrhage is free, press into the wound a pledget of sterile gauze and hold it firmly in place for a few seconds, then raise it gradually from one side and carefully watch for the exact spot from which the blood flows, or from which occurs the most profuse flow. If it comes from the dura, a stitch passed by the small curved needle already threaded will probably control it unless the dura be very badly lacerated. The author has had two cases in which the hemorrhage was so exceedingly profuse when the depressed bone was raised that he was obliged to desist, rapidly pack with iodoform gauze, and give up any further operating attempt. One case was an enormous fissure and depressed fracture in which the whole parietal bone was drawn downwards upon the cerebrum and the temporal bone fissured transversely across; the bleeding from the meningeal vessels was so profuse and from so many places that raising the bone would have meant almost immediate death. The bone was left depressed and acted sufficiently, with external plugging and compression, to control the hemorrhage. The cerebrum was so extensively torn that the man died soon after. The other case was quite an extensive compound comminuted fracture, just a little posterior and to the right of the vertex; the depressed part had torn the longitudinal

sinus. The first gentle movement of the depressed fragments was followed by a torrent of blood. He was obliged to drop the fragment back immediately and make pressure; then with a gouge and chisel to cut out some of the peripheral fixed bone; he succeeded in detaching a small fragment of loose bone near the sinus, and by gently insinuating a piece of iodoform gauze in the direction from which the blood seemed to come, he finally stopped the hemorrhage. The next day he was able to raise the depression, but the hemorrhage was again profuse; he controlled it, however, by packing gauze introduced into the rent in the sinus. The man made an uninterrupted recovery notwithstanding the very extensive depression and loss of bone. These cases show that even the most alarming hemorrhage may sometimes be controlled, and packing is the most efficient method of doing this. Such cases as these also show the necessity of having ready means of meeting these emergencies and the futility of attempting these cases by the roadside or when not prepared for them.

The fragments of depressed bone having been removed and the hemorrhage stopped, the next thing is to clean out clots and all detritus. He finds a gentle stream of warm sterile saline solution the best method of doing this, especially when the dura is badly lacerated and there has been an escape of lacerated cerebral matter. Swabbing out a cavity in the brain is a disagreeable and rough method and is apt to increase the injury and so do great harm. After this, if practicable, the dura should be sutured with fine sterile silk. If the dura cannot be brought together, and especially if the cortex has been lacerated, there is great danger of cerebral hernia resulting. In these cases he has replaced the dura with a layer of gold foil, introduced under the edges of the dura on every side and of course large enough to cover the area of bare brain left by the lacerated dura. The dura holds the edge of the foil, then by passing sutures from one edge of the dura across the foil to the other edge and tying them, it is held firmly in place. He lays special stress upon the importance of inserting the foil under the dura mater; if the arachnoid is intact it lies between the dura and arachnoid. Other operators have used the foil between the dura and cranium for the purpose of preventing adhesions to the bone. Experience has shown that in traumatic epilepsies there are nearly always

adhesions between the dura and the arachnoid and pia, and that fibrous bands seem attached actually to the cortex itself. The expedient he recommends will obviate these deep adhesions to a great extent, as well as fill in the gap in the dura. When the force applied is very great and over a very circumscribed area—as by a blow from the cork of a horse's shoe, or a bolt on a car striking the cranium—there may be a sort of punched-out wound of all the tissues and a depression deep into the cortex, as he has seen in one case. After all bone, detritus, etc., is removed, there will be a cavity left in the brain, and the cerebral tissue, semi-solid as it is, will continually gravitate into the cavity and thence outwards, in spite of all ordinary efforts to prevent it. He succeeded in controlling this, and had a rapid recovery in the case he mentioned, by making a cup of the gold foil and sinking it into this cavity in the cerebrum, about two centimeters deep; by attaching its rim to the indentations and irregularities of the inner table he anchored it, and then gave it fixity by plugging the cavity of the cup with iodoform gauze. He recommends this in similar cases and says he shall use it whenever he has a chance. The gold foil remained permanently in the cerebrum and caused not the slightest disturbance, and prevented entirely any further escape of cerebral matter. The gauze packing may be removed in three or four days.

Having dealt with the dura and lacerated brain according to the indication, the next point is to assure good drainage. Usually capillary drains of iodoform gauze or thoroughly sterilized catgut will suffice; these, while they act as capillary drains, are best placed at the most dependent part of the wound when the patient shall be in the ordinary recumbent position in bed. Gravity will assist in draining, and sometimes this is necessary in such cases. The next question is, shall the pieces of bone be replaced or not? When the fragments of bone are all badly comminuted, especially when they have been much soiled, and when their replacement may possibly interfere with drainage, do not replace them. Estes' experience is against replacing the fragments at all when they have been entirely separated; they are almost sure to become depressed, no matter how carefully and nicely they be replaced. In one case traumatic epilepsy followed after such replacement, and though it was subsequent to a second severe injury to the head, the symptoms now all point to the firm but

depressed area where the fragments were replaced, and he thinks these are causing the trouble. The man absolutely refuses to have an exploration made. Dr. Beach's and Dr. Weir's recommendation of gold foil under the cranium is better, or some of the many heteroplastic methods—such as plates of celluloid, ivory, or silver fitted into the space left vacant in the cranium—may be used.

The scalp should, as a rule, be nicely exposed and sutured, always leaving a sufficient space for the drains. Sometimes extra drains through the scalp may be used with good effect. Sterile, dry dressings should be applied and held firmly in place by careful bandaging.

The after-treatment of cases of cranial injury, followed by operation, is usually very simple if the operation has been efficient. Cases of depressed fracture or fissures of the vault are frequently accompanied by pressure signs, rather diffuse, but in many cases pointing to injury of the opposite side. In these cases subdural hemorrhage or multiple small hemorrhages, small lacerations, and severe contusion of the cerebrum in the cortex and about the corpus striatum and optic thalamus of the opposite side may be suspected. Trephining over the motor area of this side, incising the dura, and occasionally capillary drainage of the lateral ventricle, may be of service, if the original operation failed to give relief. This secondary opening should be done with a trephine or electric saw and not with a chisel, as jarring of the head should be sedulously avoided. For twenty-four hours after the operation he gives pretty full doses of ergot and the bromides; also full doses of morphine hypodermically if restlessness or sleeplessness should require it. A prime indication is to keep the patient quiet and absolutely free from pain, if possible. He never uses ice-caps or any application of cold to the head after head operations. Gauze drains may be withdrawn as a rule in forty-eight hours; gauze packing for hemorrhage, unless a sinus or one of the larger meningeal arteries has been torn, may be removed at this time also. If one of the larger vessels has been involved, about sixty hours is a safer period for packing to continue. The scalp drainage—that is, the drain through the scalp wound to the dura—if there has been considerable laceration, should be continued for a week. Recumbency, with slight elevation of the head, should continue until all cerebral symptoms are passed. Light nitroge-

nous diet should be allowed and as much water as the patient will drink. If stimulation is necessary he invariably uses strychnine, and has found that its stimulating action on the spinal cord never does harm if properly watched and the dose graded. Alcohol is contraindicated in his experience. After three days he usually gives bichloride of mercury in full doses, and if the "cerebral irritation" or cerebritis persists, ascending doses of potassium iodide, with some one of the bromides. The strictest asepsis and the best drainage must be maintained throughout.

#### ON OPERATIVE INTERFERENCE IN TYPHOIDAL PERFORATION.

ARMSTRONG publishes a valuable contribution on typhoidal perforation in the *British Medical Journal* of December 5, 1896. He calls attention to the fact that symptoms of perforation are generally described as being very distinct and characteristic. These symptoms are sudden, severe abdominal pains associated with collapse; a marked fall in the temperature, often to a point below normal; the pulse becomes rapid and shabby; the abdomen at some part is tender to the touch, and the abdominal muscles tense and rigid, and later distended and tympanitic; the patient is sometimes livid, the face covered with a cold perspiration; the extremities cold.

Too much reliance should not be placed upon the disappearance of liver dulness, although if you are familiar with the area of liver dulness in the patient under observation, the lessening of the dull area in a suspected perforation is certainly a valuable sign. Murchison mentions as other causes of intestinal perforation in typhoid, softened infarctions of the spleen, softened mesenteric glands, and rupture of ovarian abscess.

The symptoms resemble very closely those of acute appendicitis, but in the writer's experience with a number of cases in this hospital, the occurrence of perforation in typhoid is not as a rule announced by such marked and distinctive symptoms as some medical authors describe. The patient complains of pain, but it is not always sufficiently severe to require opium for its relief. There is abdominal tenderness, but it is not as great as in appendicitis, and greater pressure is required to make the patient complain. The temperature is generally lowered two or three degrees, but soon rises again; the face is anxious; and the pulse somewhat

but not markedly accelerated; it is often altered more in quality than in rate. In fact it requires careful and critical observation to determine whether in a given case a perforation has occurred or not. In some cases the symptoms of perforation may be said to be almost entirely absent. This is why house physicians so often overlook its occurrence, and leave it to be discovered by the attending physician at his next visit.

Having recognized a typhoid perforation, how should it be treated? When sure of your diagnosis, give a dose of opium; by so doing you relieve pain and arrest peristalsis, thus favoring the formation of limiting adhesions, and so far as possible preventing the spreading of the escaped matters over the abdominal cavity. Supply artificial heat by means of hot-water bottles and hot flannels, and if there are indications for it, administer a stimulant. Hot fomentations over the abdomen are generally grateful. If the patient's condition permits, ice may be applied over the tender area.

Leyden in 1884 suggested that typhoid perforations should be treated by laparotomy. In the same year Mikulicz reported a successful case of laparotomy with intestinal suture in a patient with ichorous purulent peritonitis, attributed to a perforating typhoid ulcer of the small intestine. The diagnosis of typhoid was not clear; the patient had a small right inguinal hernia. He thought himself well when he jumped out of bed, and was suddenly seized with acute abdominal pain. Laparotomy was performed on the third day for supposed intestinal obstruction. A hole was found in the ileum six millimeters long and four millimeters wide; there were no signs of injury to the bowel, and the mesenteric glands were enlarged. The opening was clean cut, and the edges of the mucous membrane were not everted.

Lücke in 1887 performed the first laparotomy undertaken with the defined object of finding and closing a typhoid perforation. The perforation occurred on the eighteenth day of the fever, and Lücke operated twelve hours later. The patient died.

Since then many operations in different countries have undertaken to close typhoid perforations, but the successes can be counted on the fingers of one hand. The first successful case that the writer finds record of was operated upon by Wagner in 1888. The patient was a woman. The perforation occurred during convalescence. The diagnosis of typhoid perforation was made, the abdo-

men opened, irrigated, and the wound in the bowel sutured. The patient recovered.

In 1890 Taylor operated, but the operation was performed ten days after the onset of symptoms. There is no proof that the case was typhoid.

In 1891 Van Hook operated upon three cases of typhoid perforation, and one patient, a woman thirty-one years of age, recovered.

In 1894 Netschagan, of St. Petersburg, did a laparotomy for typhoid perforation, and resected a portion of the perforated bowel. The patient recovered.

In 1894 Abbe performed laparotomy on a woman, aged thirty-one, who was convalescing from typhoid. The opening was sutured, the abdomen thoroughly irrigated and tamponaded with iodoform gauze; the abdominal incision was not closed. The patient recovered.

Laparotomy for the treatment of typhoid perforation has been performed six times in the Montreal General Hospital, three times by the writer and three times by his colleagues. So far he has not been able to record a success. The perforation occurred in the patient who is the subject of the author's present paper on the thirteenth day of a more than usually severe form of typhoid fever. The pain and collapse at the time of perforation were not marked; there was some vomiting. He operated eighteen hours after the occurrence of sudden abdominal pain, tenderness, and vomiting. The perforation was readily found, situated about six inches above the ileo-cecal valve; a quantity of fetid brownish fluid, pus, and gas filled the pelvis and lower abdominal zone. The perforated ileum had formed no adhesion to neighboring coils or to the parietes, but the opening was partially closed by a corner of omentum which was attached around the perforation; it separated very easily. Possibly if this man recovers it will be due to the fact of this omental adhesion limiting the escape of bowel contents. Twenty days had elapsed since the operation. The patient's condition was good in every way; he passed formed stools, slept well, and took plenty of nourishment; his abdomen was soft and flaccid, and absolutely free from pain or tenderness; temperature falling, and had a good pulse of 88.

The statistics stand at present—not counting the writer's case, whose recovery is not yet complete, but including doubtful cases—thirty operations and six recoveries; but if only those cases are included in which there

was no doubt as to the diagnosis, counting only early laparotomies, we have twenty-three operations with four recoveries. It is probable that many unsuccessful operations have been performed that have not been reported, but he thinks most of the recoveries have been recorded. Five cases have recovered after incision and evacuation of local collections of pus, and one case after aspiration of a collection of pus and gas in the cecal region.

Now in view of these results, what is our duty when brought to a case of typhoid perforation? The patient is in very poor condition for operation, suffering from the typhoid poison, with very poor reparative and recuperative power. Perforation peritonitis adds more poison. Should we add the traumatism of an operation with a little loss of blood, and anesthesia? Does any other treatment offer as good or better chances? Is there any alternative but to operate, or to hand the patient over to some one familiar with such work? The question must be answered according to the circumstances and condition of each case. If there is a clinical evidence that the perforation is in the colon, or that it is likely to remain localized, then we should wait for abscess formation. If, on the other hand, the clinical signs point to a perforation having occurred into the general peritoneal cavity previous to the formation of living adhesions, it would seem as though laparotomy, closure of the hole, thorough irrigation with normal saline solution at a temperature of 110° F., and very free drainage, offered the only hope of recovery. This should not be undertaken until the condition of collapse has passed off, nor in patients who are evidently moribund.

Perforations occurring during convalescence offer greater prospects of recovery. In this, as in the writer's previous cases, he closed the opening in the bowel by two or three rows of Lembert sutures running in the long axis of the bowel. The opening closes readily. Dr. Johnston kindly tested the closure in the two cases that died—one twelve hours, the other twenty-four hours after operation; in each case neither water nor air could be forced through the sutured part without a good deal of pressure.

The diagnosis in the case reported was confirmed by finding that a drop of the patient's blood gave the characteristic reaction when brought into contact with a pure culture of the typhoid bacillus after a modification of serum diagnosis.

#### WHEN MAY GONORRHEICS MARRY?

DR. LOWENHARDT (*Journal des Connaissances Médicales*) gives the following rules to be observed by physicians consulted by blenorrrhagics to gain medical consent to marry: As the virulence of the urethral discharge depends upon the presence of the gonococcus, the candidate should be subjected to numerous bacteriological examinations, carried out separately on the secretion of the anterior and posterior urethra. A slight secretion is not sufficient, but the urethral mucosa must be irritated in such manner as to place it in analogous conditions to those (excess in Baccho et Venere) which light up an indolent process. This result may be obtained by injecting a few drops of a five-per-cent. solution of silver nitrate into the urethra; if the discharge thus set up contains no gonococci, but is entirely made up of epithelial cells, marriage can be permitted. Another rather popular method of provoking a urethral discharge in order to establish the verity of a cure is to give an injection of 1-to-1000 bichloride solution, and to instruct the patient to drink a quart or more of beer. This would seem to be more heroic than circumstances would warrant. The presence of the numerous pus corpuscles necessitates renewed examinations and energetic treatment of this pseudo-gonorrhea. In spite of failure to find gonococci after repeated examinations, it is better to wait until the discharge has ceased entirely, and to withhold consent to marry until there can be no possibility of contagion. The extreme views of Noeggerath and Tait on the incurability of gonorrhea in the male are too often and too clearly refuted by practical experience to merit serious consideration. Latent gonorrhea, in the etymological restriction of the adjective to "lying hidden," has no existence. If the disease exists, it can always be discovered.—*Medical Record*, Dec. 19, 1896.

#### AMBULANT TREATMENT OF FRACTURES OF THE LEG.

MARTIN (*Philadelphia Polyclinic*, Jan. 2, 1897) presents a communication with the above title. The method of treatment consists in so applying the plaster dressing that a patient, instead of being confined to bed for five or six weeks, can get about and attend to any light occupation. The dressing had been applied to twelve patients in the last six

or eight months. The dressing was employed in upwards of thirty cases and the results were good. There were two cases in which the results were not thoroughly satisfactory, but in these the reporter did not apply the dressing personally. One was an instance of Pott's fracture. The deformity was not greater than is often noticed after treatment by the fracture-box, but there should have been none. The other was one of compound fracture, for which the patient was operated on. The wound healed kindly at first, but later it broke down and the fracture was found to be ununited. The bone was then cut down upon, and a portion of the tibial shaft, about two inches, resected. A few days after the operation, as the operation wound was running a sterile course, Dr. Martin directed an ambulant dressing to be applied. The patient was up and walking five days after the operation, and he apparently did well, the bone uniting, although there was some deformity. Martin has never used the dressing for fractures of the bone above the knee, and, with the exception of the last case, all have been simple fractures.

The first patient was a boy who was run over by a bicycle, and both bones of the leg were broken at the middle third. There was no difficulty in replacing the bones in good position, and an ambulant dressing was put on a few days after the injury. After the plaster was applied there was no pain, and the patient has been walking ever since—that is seven weeks ago. There seemed to be less stiffening and after-trouble than is common when the fracture-box is employed. The boy has been very comfortable and has been saved a long confinement in bed. The first dressing applied broke, because of poor plaster, and a second one was put on about ten days later.

In the second patient, a boy, the first dressing was poor and a second had to be applied; the latter was worn for five weeks. The union is perfect and there is no disability.

The third case was one of fracture of both bones of the leg at the middle third, during a fight. The patient began walking the day after the application of the dressing. He came to the dispensary to be dressed, and was saved several weeks in bed.

The fourth case had a Pott's fracture; the patient began walking the next day, but had some pain.

The last case was in an old woman, who fell down stairs some three or four months before, breaking the upper third of the tibia

and fibula. There was very little deformity, and the dressing was applied promptly. She had less use of the dressing than any patient that Dr. Martin has thus treated. She could not walk without a crutch or chair. Three weeks elapsed before she went home. She did not complain of pain, but seemed unable to manage the large, heavy dressing. The day following the application of the dressing—the second after her accident—Dr. Martin took her by the hand and led her up and down the ward, but the walking was not rapid or easy. Perhaps the best thing the dressing did for this patient was to shorten her stay in bed and allow her to go home and walk about one or two weeks sooner than she otherwise would have done. She presented absolutely no deformity; nor did any of the cases.

The cases presented were not selected by any means, and represented very nearly what can be expected from the dressing. The first proposition to treat fractures by the ambulant method was made by Bardeleben in 1894, and, following him, a number of German surgeons tried it. Bardeleben reported upwards of 111 cases. Some of his colleagues reported a number of others, so that the total number was 200. Since that time Dr. Martin has had upwards of thirty cases of his own.

The Germans apply the ambulant dressing not only for fractures of the leg, but also for simple and compound fractures of the thigh. The principle on which this dressing is applied is that of fixation and shifting of support. Given a fracture of one or both bones of the leg, as soon as the weight is thrown on the foot there is, of course, a tendency to overlapping of the bones. If the weight of the body could be carried from above the fracture to the ground by external supports, as by means of a plaster case passing from the knee-joint to below the sole of the foot, the tendency to overlapping would at once be corrected. If the weight of the body could be kept from causing overriding of the fragments, and at the same time the fragments fixed in good position, there seems to be no good reason why patient should not use his leg. This is accomplished by the so-called ambulant splint; the plaster is so applied that the weight of the body is carried from the tibial tuberosities just below the knee to the reinforced portion of the dressing lying below the sole of the foot, pressure upon the malleoli being avoided by abundant cotton padding. This dressing fixes both the joints

contiguous to the fracture. It is perhaps open to a serious objection, as it entirely prevents the use of massage. It is inapplicable to certain cases, *e.g.*, when there is great swelling, when the shape of the leg is such that the weight cannot be carried from the tibial tuberosities to the rigid dressing that envelops the leg (this is particularly the case in very fat women with small bones). In most instances of simple fracture of the leg, when reduction is possible, either with or without ether, and when the swelling is not marked, the dressing is the most satisfactory that can be used.

The dressing should be applied as soon after the fracture as possible; it requires abundant padding with some elastic material; it must be so arranged that the plaster does not press into the malleoli, and the plaster must be neatly fitted below the knee; it should be worn from four to six weeks. On the day following the application of the dressing, the patient is gotten up with the help of an assistant or a friend, who takes him under the arm and assists him in walking up and down the ward. The Germans use an apparatus very much like the walking device provided for children, the patient standing inside a sort of cage which is on wheels. In a day or so walking is possible with two crutches; in another day, with one crutch; and in a week the patient can usually get along with a cane or without any support. It is scarcely rational to apply this dressing to a hod-carrier and expect him to be able to continue his employment at once; but a man can attend to ordinary business pursuits.

Another advantage of the dressing is that less atrophy follows than after the use of the ordinary fracture-box or plaster dressing. The fracture-box is a poor dressing. Even if the patient is lying in bed the plaster is best. The atrophy is a manifestation of a reflex neurosis, as has been proved by experimental research. The great advantage inherent in the plaster dressing is that it enables the patient to be up and about (and every one realizes how irksome it is to stay in bed when it is not absolutely necessary), and may, perhaps, save these patients four or six weeks of lying on their back.

As to the direct method of applying the dressing: In the first place the plaster must be fresh, and that is often a very great trouble in plaster bandage—it is better made in a coarser mesh of gauze than that used for the ordinary surgical bandage; a lot of cotton batting should be provided; and the fracture

must be reduced. A mistake is often made in not etherizing more frequently than is done in the treatment of fractures. The first essential is thorough reduction. When there is swelling and the patient is sensitive there is a great temptation to trust that reduction is accomplished without making this perfectly apparent. In the majority of cases ether should be administered in applying this plaster bandage. Ether should always be given when it is not absolutely certain that the bones are in proper position. The leg is then enveloped in a flannel roller, as is customary in the application of all plaster dressings; the cotton is wrapped about and then the plaster is applied. For the purpose of flanging out the lower part of the plaster and giving a little more strength, the reporter uses slightly flexible steel rods, such as are employed in orthopedic work for bracing shoes. They are flexible, so they can be molded to the desired shape. In putting on the dressing it is essential that the toes should point a little up; if they drag they are liable to strike things; the heel should be a little lower than the toes. A child of eight or ten years of age requires a flannel bandage two inches wide; the foot is covered in, no reverses being employed. In putting on the cotton batting it is well to tear it off the roll of the required width; it then rolls out very much like a bandage. The malleoli are thickly padded, so that the plaster may be prevented from falling in and pressing at these points. At the knee-joint where the plaster should bear pressure the padding is thinner. If the surgeon intends to take the plaster off himself it is well to partly cut it, and for that purpose a lead strip is needed. The sole of the foot is padded with a mass of cotton at least three inches thick. The plaster is now ready for application; the first two turns take in the padding on the sole and keep it in the middle line. In applying this bandage a little tighter pressure is employed than with an ordinary plaster bandage, as, because of the thick padding, the parts will stand it. When the patient is placed under the influence of ether, he must be kept under until the dressing is hard. The bandage runs up to a little above the knee. Having closed in the cotton the external metallic splints are applied; these are molded to the part and covered in with more plaster. The patient is kept perfectly quiet and the toe is held up until the plaster hardens. In another twenty-four hours the patient is allowed to put the foot to the ground.

While the plaster is still moist a knife is run along the line of lead strip, leaving several bridges, which should be marked by pencil before cutting. When the time comes to remove the plaster the bridge is simply cut through by a pen-knife and the dressing will spring off.

SEVEN CASES OF PERFORATING GASTRIC ULCER TREATED BY OPERATION, WITH THREE RECOVERIES.

Under this title a valuable paper appears in *The Lancet* of December 5, 1896, by ARTHUR E. BARKER. He says that among the most recent advances in abdominal surgery none is more interesting or more likely to yield good fruit than the operative treatment of perforating gastric ulcer. This hitherto terribly fatal accident is now shown to be well within the reach of surgery if taken in hand promptly; and there seems to be good reason to hope that as time goes on our achievements may be crowned by a success which as yet we can hardly estimate, for just as in the case of other intra-abdominal lesions the study *in vivo* by the operator has cleared up many pathological and clinical questions impossible of solution by those who only had an opportunity of examining regions and tissues after death, so may it be in the case of gastric ulcer.

The condition of the patients at the beginning of the operation varied. In the second case there was no shock and the color was very good, but the temperature was  $102.2^{\circ}$ , and the pulse 136 and intermittent; the abdomen was not markedly distended. In the first case there was not much shock; the temperature was  $103.2^{\circ}$ , the pulse 120, and the abdomen was not distended. The same was true at the time of operation in the third case, though the perforation produced shock. All of these recovered. In the fourth case, too, in which the patient lived fifteen days, there was not much shock although the temperature was  $102^{\circ}$ , the pulse 116, and the abdomen somewhat distended thirty-two hours after perforation. There was much collapse in the sixth case; the temperature was  $99^{\circ}$ , the pulse 140, and the abdomen generally distended twelve hours after perforation. Extreme collapse was also present in the fifth case, with the pulse 160 and the respiration 60, the abdomen being greatly distended all over, twenty-eight hours after perforation. Both of these cases died soon after operation. The three cases which re-

covered were operated on respectively at eight and a half, eighteen, and seven and a half hours after the accident; the other four at thirty-two, twenty-eight, twelve, and seven hours after.

In all seven cases the perforation was on the anterior stomach wall; the largest was only half an inch across. There was no evidence in any of a second perforation. The duration of the several operations was: In the first case, one hour and twenty-five minutes (recovered); in the second, just two hours (recovered); in the third, one hour and twenty-three minutes (recovered); in the fourth, one hour and a quarter; in the fifth, one hour and five minutes; in the sixth, one hour and a quarter; and in the seventh, one hour and twenty minutes. The last four died.

In regard to the operations themselves, they were carried out on the same lines except in the fourth case. Everything was done as quickly as possible; a median incision was made in all; in three a transverse cut through the left rectus muscle was added to this, the perforation being difficult to reach; in one an inguinal incision had been previously made which probably facilitated the cleansing of the pelvis very materially. In cleansing the peritoneal cavity dry sponging without flushing of any kind was employed in all; in doing this particular care was observed to carry the hand and sponge between the liver and diaphragm in order to wipe away lymph, fluid, and food. In his first case (Case 4) this point was omitted, with the result of a left subphrenic abscess. Taught by this, he was more careful in all the other cases and was surprised in each by the amount of matter which could lodge between the liver and the diaphragm. Round and behind the gall-bladder also required special cleansing, as well as the flanks and pelvis. There was no very special difficulty in carrying the hand into all these regions through the median incision. After a large experience of flushing the abdomen, he prefers dry sponging for this class of cases. A drainage-tube was inserted through a special hole in the flank in two cases, but in each appeared to do but little work, and he thinks now might have been dispensed with except in the third case, where a subphrenic abscess formed and had to be opened between the ribs. The anterior wound was drained with strands of iodoform gauze in four cases, and with the best results. One strand reached deeply between the liver and diaphragm on

each side, another to the suture in the stomach, and a fourth down behind the gall-bladder. They remained *in situ* until the fifth or sixth day, when there was always some difficulty in removing them. But he has been greatly impressed with their value; they drained well, and on removal the edges of the wound came together wonderfully. In the second case, the scar had all the appearance of one healed by first intention, without the least bulging. In no case was the ulcer cut out; the edges were simply folded well in and the closing silk stitches were deeply inserted in one or two rows by means of round sewing needles.

In the after-treatment great reliance was placed on feeding by the mouth. Small repeated doses of egg albumen and water, of brandy, beef-tea and chicken broth were begun as soon as the patient had recovered from the anesthetic. But besides this, peptonized suppositories were introduced into the rectum, alternating every two hours with five ounces of hot water.

From the experience gained in these cases he is inclined to think that success or failure depended in the first place upon the moment after perforation at which they were treated. In the next place the condition of the stomach contents which escaped among the intestines must have influenced the result. In the second and third cases the fluid found round the perforation was thin and without visible fragments of food; it was also slightly alkaline. The characters of the fluid in two other cases were the same to all appearance; one of these recovered and the other lived fifteen days. In the three remaining cases, where solid meals had been taken shortly before, large fragments of food (potatoes and greens) were present among the intestines and were producing much irritation, as evidenced by the presence of abundant lymph and dirty serum. Of course this produced much more profound shock and great distention. Whether in these two cases the abdomen could have been better cleansed by flushing is a question easily answered. Very voluminous and prolonged flushing would probably have done more in carrying away debris of food than simple sponging with the hand; but in the state in which these patients reached the operating-table they would not have tolerated any prolonged operation. As it was, one died of shock four hours after, where the operation only lasted sixty-five minutes. On the whole the writer formed the impression that dry sponging, as employed

in all these cases, is preferable to flushing; but then it must be carried out with method.

In the worst of these cases where there was terrible shock before the operation, and in another case, the pulse and general condition improved greatly on the opening of the abdomen and the escape of the gas and fluid pent up under great pressure. This ought to encourage us to operate where collapse is present rather than wait on the chance of its subsidence. But it should also be noted that handling of the stomach produced violent vomiting, which only ceased when the chloroform was pressed. It was necessary to evacuate the stomach by pressure in all cases, and he thinks this is better done with the hand through the perforation than by washing out, which is tedious. As to the after-treatment in these cases the immediate feeding by the mouth appeared to be as beneficial as after other operations on the stomach. It is hard to imagine how this could be injurious at first, while the stitches hold; and the benefit in arousing the patient from collapse is a justification for running some risk. We should feel more anxious about mouth feeding after two or three days than at first, for then the stitches might be cutting. Of course, food and plenty of fluid must also be given by the rectum at the same time. Finally, the writer has been careful in the two cases which recovered to keep the patients for a long period in bed under strict treatment for the gastric ulcer; for though the perforation may soon be soldered up after stitching, there is good reason for believing that the gastric ulcer and the generally vicious condition of the digestion takes a long time to repair, as was evidenced in one of the author's cases.

In the two cases referred to the patients are still under observation. One is seen daily and appears now, four months after the operation, to be in excellent health; she is in service again and doing her work cheerfully and well. The first case was also quite well and in service when last heard of; the third case is still in hospital, but going on well more than a month after the operation.

#### INJECTION OF IODINE IN SURGICAL TUBERCULOSIS.

CAMPANINI (*II Policlinico*, Oct. 1, 1896) gives several examples of the results of Durante's method of treatment in various cases of surgical tuberculosis. The author gives details of two cases of tuberculous joint disease—in one fifty-three injections,

some intra-articular and some intramuscular, were given; in the other forty-five injections were given. In each case a cure was effected. In tuberculous glands, especially if unassociated with a suppurative periadenitis, the iodine injections gave good results; two cases of tuberculous peritonitis were treated with decided advantage by the same method. In addition to the above the author also practiced Durante's method in two cases of lupus and one of tuberculous orchitis and epididymitis. Time alone can prove whether relapses occur with less frequency after the iodine treatment, but as far as he has tried it the author is strongly in favor of it in suitable cases.—*British Medical Journal*, Dec. 5, 1896.

#### VESICO-INTESTINAL FISTULA TREATED BY TRANSVESICAL SUTURE.

POUSSON (*L'Union Médicale*, No. 51, 1896) had a patient brought to him suffering from cystitis complicated by pneumonia. This latter symptom was attributed to ammoniacal fermentation and had lasted for three years; it was so pronounced that the patient was unable to use a public urinal. Finally fecal matter appeared mingled with the urine, thus rendering diagnosis absolute.

Endoscopic examination showed an ecchymotic spot, thus apparently locating the fistula. Hypogastric cystotomy was performed, but the opening was not found in the region of this spot of ecchymosis; the fistula was placed above the opening of the right ureter. The vesical edges were freshened and sutured. The immediate result was excellent, but on the third day gas passed by the urethra, and the following day some fecal matter escaped; this continued for six days, then gradually lessened and finally cure was accomplished.

#### TREATMENT OF FRACTURES BY MASSAGE.

FÉVRIER (*Revue Médicale de l'Est*, 1896, 13, p. 385) states that as a result of massage in the treatment of fractures, there is immediate disappearance of pain, diminution of swelling, rapid restoration of function; quick formation of callus preceding the bony union, which is likely to be voluminous; free establishment of motion, and absence of muscular atrophy.

In carrying out the treatment the hands of the masseur should be surgically clean; the skin which is rubbed should be lubricated with sterile vaselin. The first day longitudinal rubbing is practiced, avoiding the seat

of fracture; circular rubbing is indicated on the following days. The thumbs and the palms of the hands are not employed until the fourth or fifth day. Passive motion is practiced at the neighboring joints. The treatment should occupy about twenty minutes.

#### SUCCESSFUL ABDOMINAL NEPHRECTOMY FOR RUPTURE OF THE KIDNEY.

At a recent meeting of the Clinical Society of London, WALLIS (*Lancet*, October 31, 1896) reported the case of a man twenty-two years old, who had fallen from a ladder a distance of twelve feet upon a spiked railing. Though collapsed and evidently in pain, consciousness was not lost. The abdomen was rigid and rather distended. On examination it was found that one of the spikes, three inches in length, had pierced the abdominal wall nearly an inch below the tenth costal cartilage on the right side; the opening in the skin ran downward and inward, and the finger passed into the wound could be pushed on into the abdominal cavity. Soon after admission to the hospital the patient passed a pint of pure blood by the urethra. He was at once prepared for operation, and an incision made from the lower end of the punctured wound downward to the right semilunar line. A lacerated wound of the peritoneum came into view, through which the bruised intestines presented. The peritoneal wound was enlarged and large masses of blood-clots were turned out of the abdomen. Sponges were inserted and the sides of the abdominal wound held apart by two long silk ligatures. The under surfaces of the liver and the gall-bladder were exposed and found intact. The intestines in the track of the wound were bruised, and one piece of small intestine presented a tear in the external coats, through which the mucosa bulged. At the bottom of the cavity the kidney could be felt, torn almost in two; blood welled up through the wound at a great rate. The left kidney was found intact in its normal situation. The peritoneum was now divided along the outer edge of the ascending colon, and this portion of the gut pushed in toward the middle line; the left hand was passed in behind the colon, the kidney rapidly freed and brought out of the wound. The ureter was clamped, tied, and cut, the vessels were treated in the same way, and the kidney was removed. The deep muscles were considerably lacerated and bled freely. Sponges were temporarily

inserted and the abdominal cavity was washed out with saline solution. The wound was packed with iodoform gauze in strips, and dressed with cyanide gauze and blue wool, and bandaged. The patient was greatly collapsed after the operation, but reacted well during the following twenty-four hours. The wound healed without complication, and the ultimate recovery was perfect. For two days following the operation the urine contained blood, and for twelve days albumen. The quantity of urine passed in twenty-four hours averaged between forty and fifty ounces. It was pointed out that in the past rupture of the kidney had been attended with a mortality of thirty five per cent.—*Medical Record*, Dec. 19, 1896.

*CONTUSION OF THE BELLY FROM THE  
KICK OF A HORSE, FOLLOWED BY  
HEMATURIA, PERITONITIS  
AND SPONTANEOUS  
CURE.*

CAMUS (*Archives de Médecine et de Pharmacie Militaires*, No. 12, 1896) reports the case of a dragoon who was kicked in the left flank by a horse. The injury caused brief loss of consciousness followed by hematuria, vomiting, fever, meteorism, suppression of the liver dulness, extreme tenderness over the entire belly (most marked in the left flank and abdominal facies), and cyanosis, the pulse running on the fifth day to 120. Thereafter symptoms ameliorated and the patient recovered entirely.

As to treatment, the physician rejected from the first the aid of laparotomy; he applied leeches externally, and withheld food for several days, employing hypodermic injections of morphine with caffeine.

sult of this stimulation has been an improvement upon the volume for 1896, good as that one was. Most of the collaborators in this volume were also collaborators in the volume for the preceding year, with the notable exception of Dr. Hardaway of St. Louis, whose place has been taken by Dr. L. A. Duhring, than whom no one has a higher reputation as a dermatologist.

In the brief space which we have at our command it will not be possible for us to mention the various authors who have brought aid to Dr. Gould in his undertaking; and an undertaking it must have been when we consider that this volume contains nearly 1300 pages of large size, and that its indexing requires no less than sixty-two pages. This index is more accurate than that of the earlier issue and is so full and complete that information which one seeks to obtain from the body of the book is easily found, an advantage which adds greatly to the value of any scientific work. From time to time as we read over the pages we notice interesting additions to the topics under consideration made by the collaborator, his advice or criticism being enclosed with editorial brackets. At the bottom of each page are copious and, so far as we can see, reliable and accurate references to the literature which has been utilized by the collaborator.

We bespeak for this book a most cordial reception by the profession, for any book which is so useful should be well received.

TWENTIETH CENTURY PRACTICE AND INTERNATIONAL ENCYCLOPÆDIA OF MEDICAL SCIENCES. Edited by Thos. L. Stedman, M.D. In 20 volumes. Volume X: Diseases of the Nervous System. New York: William Wood & Co., 1897.

Volume X is published before Volume IX because the manuscripts for Volume IX were delayed. This volume is in all respects and general appearance identical with those which have preceded it, and deals entirely, as we have stated in giving the title, in the consideration of the Diseases of the Nervous System. Six authors contribute the 860 pages which are comprised in the book, namely: Sanger Brown of Chicago, Charles L. Dana of New York, Joseph Collins of New York, Charles S. Féré of Paris, Howell T. Pershing of Denver, and Bernard Sachs of New York.

The first article, upon Diseases of the Brain, is by Dr. Joseph Collins, who although one of the younger neurologists, is nevertheless qualified by experience at home and abroad to discuss the important topic which

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. A Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine. Collected and Arranged with Critical Editorial Comments by a Large Staff of Collaborators under the General Editorial Charge of George M. Gould, M.D. Profusely Illustrated.

Philadelphia: W. B. Saunders, 1897.

We are told in the Preface to this second issue of the Year-book that the cordial reception given the Year-book of 1896 has stimulated the editors to renewed enthusiasm in the preparation of the present volume, and from an examination of the pages of the present issue we can readily see that the re-

has been assigned to him. The first sixty-four pages of his article are devoted to the discussion of the important subjects of the morphology and anatomy of the brain and cerebral localization, in which he gives us a good summary of the knowledge of these important matters, and then adds a bibliography which covers nearly five pages and refers to most of the best researches which have been made upon these subjects in this country and abroad. He then proceeds to a discussion of the various forms of encephalitis and brain abscess, paying considerable attention to the differential diagnosis and the treatment, and this and all his subsequent articles are added to in value by the copious bibliography which he gives us. He briefly considers the important subject of the infantile cerebral palsies, and illustrates his text by numerous illustrations of patients suffering from the diseases under consideration. He then discusses multiple sclerosis in its various forms, hydrocephalus and parasites of the brain, thrombosis of the dural sinuses, diseases of the cerebellum, and then proceeds to a consideration of lesions in the medulla oblongata, including the various forms of bulbar paralysis and associated neuritis of the bulbar nerves. His article covers 260 pages.

In the succeeding article Dr. Dana, in the short space of thirty-seven pages, considers Intracranial Hemorrhage, Embolism and Thrombosis, including Apoplexy and Hemiplegia. No bibliographies are added to fortify the statements made by the author, and it will be seen at a glance that in the brief space which we have named it has not been possible for Dr. Dana to consider, in as capable a manner as in the article which we have just quoted, the important topics which have been assigned to him and any one of which might with advantage have covered the total number of pages which we have named.

Dr. Sachs' article on Tumors of the Brain is fifty-four pages in length, including its bibliography of two pages, and is a first-rate summary of the subject of which it treats, for although it is not as exhaustive as one would expect to find in such a volume as the one before us, Dr. Sachs has a happy way of expressing himself which renders everything he writes readable.

The fourth article, upon Diseases of the Meninges, is also by Dr. Collins, and is as exhaustive and valuable as the first one we mentioned, covering over ninety pages.

The articles upon Hysteria and Epilepsy and Spasmodic Neuroses are by Féré of Paris, and while they are not particularly strong so far as the therapeutics are concerned, add very considerably to the value of the book.

The article upon Neurasthenia, which covers but twenty-four pages, is by Dr. Dana, and is also far shorter than we expected to find in so exhaustive a work, for surely this topic is one deserving of graphic description and requires much space for its proper consideration.

The next article is by Dr. Pershing of Denver, upon The Disorders of Speech, and gives an interesting summary of much that we know concerning the curious symptoms associated with aphasia and collateral subjects. It covers fifty pages.

The final article in the volume, upon Disorders of Sleep, by Dr. Sanger Brown, which covers thirty-three pages including its bibliography, might also have been considerably enlarged and the topics dwelt upon more fully with advantage.

With each succeeding volume our opinion of this magnificent undertaking, which we at first regarded with considerable suspicion as to its ultimate success, improves, and we find among our medical friends that the profession is becoming more and more impressed with the necessity of purchasing this series.

**DISEASES OF INFANCY AND CHILDHOOD.** For the Use of Students and Practitioners of Medicine. By L. Emmett Holt, A.M., M.D. Copiously illustrated. New York: D. Appleton & Co., 1897.

Dr. Holt has presented us with a large and exhaustive work on Pediatrics, one which because of its size and scope is qualified to lay claim to the position of representing the best and most recent views concerning this important part of medical study. It remains for us, therefore, to examine his pages with interest, to see whether he has so utilized the space at his disposal as to accomplish the object which he has placed before himself in the compilation of such a volume.

One of the first things that strikes us as we read the pages is the style. While we have no one reason for expressing this opinion, we venture to state that a very considerable portion, if not all, of the book has been dictated to a stenographer, since it lacks the smoothness and conciseness which comes of wielding the pen direct, and possesses the rather short and dogmatic sentences which one has recourse to in dictating. We have met with a number of books recently in which

it seemed to us that this criticism obtained, and we think it a matter of regret that authors when taking the time and trouble necessary for the gathering together of their facts should mar their completed work by the avoidance of the necessary manual labor.

It will not be possible of course to go over the book page by page. We think that those who are enthusiastic in the discussion of infant feeding will be quite well satisfied with the chapters upon the infant's Dietary and Nutrition. From first to last the most captious critic cannot find fault with the illustrations, many of which are original and nearly all of them very well executed. By far the worst illustration which we have met with in the book is one which is designed to show epithelial desquamation of the tongue, which looks more like a horse's skull than any other object with which we are acquainted, and which utterly fails to add anything to the clearness of the text. The very good illustration of gangrenous stomatitis makes up, however, for this defect; and the plate representing the various sizes and capacities of the stomach at different ages seems to us a very good one. A considerable number of the cuts we recognize as having been taken from Dr. Holt's article in Keating's *Encyclopædia of Children's Diseases*, and several plates are also taken from the same source, although the credit is not given in their legends. It is a matter of surprise that Dr. Holt has devoted only twenty-two pages to the Gastric Disorders of Infancy and Childhood, for certainly these disorders form a very large proportion of the cases which we meet with in practice. Thus the subject of gastric dilatation covers only one and a third pages. While it is true that this condition is not so frequently met with in children as in adults, it occurs with sufficient frequency to justify more exhaustive treatment.

Ulcer of the Stomach, which is a much more rare condition and almost invariably results from tuberculosis or the ingestion of poisons, covers about one page.

In the article upon Diseases of the Digestive System, in connection with the intestines, Dr. Holt states that the highest mortality from intussusception occurs in the first year, a fact which is, of course, universally recognized by those who have studied this matter statistically. The statement, however, that such a lesion is not a common one, seems to us hardly correct in view of the fact that according to the statistics of Leichtenstern

and Bryant forty per cent. of all cases of intestinal obstruction are due to this cause. In the discussion of the statistics given by Dr. Holt the statement is not made as to whether they have been collected by himself or whether he has taken them bodily from some other author. If they have been collected by himself he has certainly not gone as exhaustively into the subject as would be possible, and from what he states in his text he has evidently relied almost entirely upon the statistics of Treves in his discussion of the subject. That the cases may be his own, however, seems to be indicated by the fact that he speaks of one of "my own cases" when discussing the total number of patients suffering from intussusception and the symptoms which they manifest.

In regard to the question of the termination of intussusception Dr. Holt states that the condition may be cured spontaneously by sloughing of the invaginated part, but that such a result is rare at all ages and is almost never seen in infancy. While it is correct to state that such cases rarely ever reach a cure it might have been well to add that sloughing of the invaginated portion of the intestine is by no means rare, and according to the researches of Leichtenstern, out of 408 cases 149 sloughed and 61 recovered. In the second edition of this book we think it would be well for Dr. Holt to include not only the statistics of Pilz, which were collected in 1870, but also those of Leichtenstern, Bryant, and those which will be found gathered together in the Fiske Fund Prize Essay of 1890 upon "Injuries and Obstruction of the Intestine."

The only other criticism of the book which we have is that the portions of it devoted to therapeutics are not as full as we think the general practitioner would like to have them. Aside from this, the remaining articles seem to us to be worthy of great praise.

It must not be thought from anything that we have said that this book is not worthy of the position which we named for it at the beginning of this review. Dr. Holt's wide clinical experience, the beautiful work which he did in connection with his article upon "Diseases of the Intestine" in Keating's *Encyclopædia*, and the numerous contributions which he has made to the literature of pediatrics, renders anything which he may write worthy of acceptance and respect by his professional brethren; and the book is to-day without doubt the best single volume and single author work upon Diseases of Children which is published in this country.

**TWO HEALTH SEEKERS IN SOUTHERN CALIFORNIA.**  
By William A. Edwards, M.D., and Beatrice Harraden.

Philadelphia: J. B. Lippincott Company, 1897.

This little book, the object of which is well described in its title, has been written by Dr. Edwards largely from a semi-medical point of view, and by Miss Harraden from a purely lay point of view, for the purpose of describing the advantages and beauties of Southern California as a health resort. It contains comparative temperature tables for San Diego and its neighborhood and the great cities of the United States, and will convey to the health seeker who is thinking of going to the Far West accurate and interesting information in pleasant text.

Miss Harraden, who is well known as the author of several contributions to literature, the most famous of which is "Ships that Pass in the Night," has written the first and fourth chapters, and Dr. Edwards has contributed the rest of the volume, which consists of eight chapters. The chapter by Miss Harraden on "Outdoor Life for Women" will be read with interest by invalids of the gentler sex.

The book is dedicated to Dr. George E. de Schweinitz, of Philadelphia.

**ANOMALIES AND CURIOSITIES OF MEDICINE.** By George M. Gould, A.M., M.D., and Walter L. Pyle, A.M., M.D.

Philadelphia: W. B. Saunders, 1897.

This large volume of nearly one thousand pages, including the index, is another monument to the extraordinary literary industry of Dr. Gould, its chief compiler, whose previous literary works we have had occasion to review a number of times in the THERAPEUTIC GAZETTE. It is composed of eighteen chapters, which deal with Genetic Anomalies, Pre-Natal Anomalies, Obstetric Anomalies, Prolificity, Major Terata, Minor Terata, Anomalies of Stature and Development, Longevity, Physiological and Functional Anomalies, Surgical Anomalies of the Head and Neck, of the Extremities, of the Thorax and Abdomen, of the Genito-urinary System, Miscellaneous Anomalies, Anomalous Instances of Disease, of Skin Disease, Anomalous Nervous and Mental Diseases, and Historic Epidemics. There is scarcely a page in this volume that does not contain in addition to its copious text and illustrations a large number of references, varying from two or three to twenty or more. A careful examination of the volume reveals the fact that Drs. Gould and Pyle must have devoted an enormous amount of time and literary research to its production, but we cannot

avoid a feeling of regret that so much literary ability and the exercise of the power to analyze medical literature should not have resulted in the production of a book of more value in the alleviation of disease. An accumulation of statements concerning and pictures representing bearded women, monstrosities in the way of flesh and wasting, and of cases of perverted sexual and other functions is not, we think, a particularly edifying addition to medical literature, and very few if any of the cases cited will aid materially in the diagnosis of unusual forms of disease. Certainly a picture of a tattooed man is not a medical curiosity, and we do not see any use in describing a case in which some students, presumably during a drunken frolic, inserted a pig's tail into the rectum of a prostitute. We notice that a number of illustrations in this volume have been very properly taken from other well known works, as for example some of the pictures of malignant growths from the American Text-book of Surgery. With Dr. Gould's never-ceasing industry we look forward to the production of other volumes from his pen which, like his Classical Dictionary, will reflect more credit than this one upon his literary ability and medical experience. To those, however, who are fond of studying subjects such as are discussed in this volume, we can cordially recommend it as being—what it professes to be—the most exhaustive and accurate summary of medical curiosities to be found in any language.

**A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD FOR DIAGNOSTIC PURPOSES.** By Richard C. Cabot, M.D.

New York: William Wood & Co., 1897.

Those who were engaged in microscopical work in connection with clinical medicine fifteen or twenty years ago would hardly have believed at that time that a useful and not overwrought book of over 400 pages could be contributed, at this time, upon the clinical examination of the blood; and yet Dr. Cabot, whose work on the examination of the blood is well recognized as being first-class, has succeeded in presenting us with an accurate summary of his investigations and those of many other observers in this volume. To a large extent it consists of a record of his own examinations of the blood and of the examinations which have been made by a number of personal friends.

In regard to the myelocytes of Ehrlich, Dr. Cabot tells us on page 55 that they are peculiar to certain diseases and are occasional

visitors to the blood on the border-land between pathological and physiological states. But on page 144, in the discussion of leukemia, he says that myelocytes are exceedingly numerous, and very properly emphasizes the view that they are of marked diagnostic importance in the study of this disease in its spleno-medullary form. While these two statements are not directly contradictory it seems to us that his first statement if true is a little too sweeping. The plates, of which there are a number, are by Funke of Leipsic, and while very good, are hardly up to the standard which he set for himself in the plates which he made for Thayer and Hewetson in their well known monograph upon Malarial Fever.

The book apparently does not attempt to present a careful analysis and summary of the results which have been reached so far by hematologists, although their work is referred to constantly, but it seems to reflect rather the opinions and experiences of the actively engaged blood examiner. Credit is given by the author to a large number of first-rate monographs which have been published abroad and in this country by other investigators. A copious bibliography, in which some of the text-books which consider the blood are discussed, closes a volume which should be in the hands of every one engaged in clinical medicine.

Dr. Cabot dedicates this volume, the first exhaustive one written upon the blood in this country, to Dr. William Sidney Thayer, of Johns Hopkins University.

**A TEXT-BOOK UPON THE PATHOGENIC BACTERIA FOR STUDENTS OF MEDICINE AND PHYSICIANS.** By Joseph McFarland, M.D. With 113 illustrations. Philadelphia: W. B. Saunders, 1896.

The author states in his Preface that his book is "intended to convey to the reader a concise account of the technical procedures necessary in the study of bacteriology, a brief description of the life-history of the important pathogenic bacteria, and sufficient description of the pathological lesions accompanying the micro-organismal invasions to give an idea of the origin of symptoms and the causes of death."

Only such bacteria as have been proven to be pathogenic by the lesions or toxins they engender have been described, the method of distinguishing such micro-organisms from others which are non-pathogenic being given as fully as is practicable. It may be said that McFarland has succeeded in producing a text-book which can be particularly com-

mended for the clearness of its writing and the directness of its teaching.

The illustrations are admirable and ample. There is no book of its class which will be found as thoroughly satisfactory to practitioners and students as this.

**LEPROSY AND THE CHARITY OF THE CHURCH.** By the Rev. L. W. Mulhane. New York and Chicago: D. H. McBride, 1897.

This is a little brochure on the subject which is given on its title-page, with pictures of lepers, of the chapels which have been built for them to worship in, of the missionaries who are working in that field and of those who, having contracted the disease, have passed away. To those who are interested in leprosy or missionary endeavor for the benefit of these subjects of a horrible disease, the volume cannot fail to be of very great interest; and while it is not a distinctly medical work, there are enough medical facts in it to make it of some value to the practitioner.

**AUTOSCOPY OF THE LARYNX AND TRACHEA: OR DIRECT EXAMINATION WITHOUT A MIRROR.** By Alfred Kirstein, M.D., Berlin. Translated by Max Thorner, A.M., M.D. Philadelphia: The F. A. Davis Publishing Company, 1897.

We are told on the title-page that this little book after its translation has been still further revised by its German author. Its design is to describe a method by which physicians may examine the larynx and trachea without the use of the ordinary laryngoscope. After the perusal of its pages we are inclined to think that while the descriptions which it gives are perfectly possible of application, physicians will continue to use the laryngoscope quite as frequently as before. It is, however, an interesting contribution in that it describes what may be done by skilful technique.

### LONDON LETTER.

By ST. CLAIR THOMSON, M.D., M.R.C.P., F.R.C.S.

Death is still busy among the leaders of our profession, and not a month—hardly a week—passes without the record of the departure of one of the epoch-makers of medicine in the Victorian age. Now I have to record the death of Sir Spencer Wells, full of years and honors. His name is known throughout the world of abdominal surgery,

and will always be associated with the history of ovariectomy. It is difficult to realize now-a-days the opposition he met with, and strange to read that in his first publications he had always to introduce the names of those present at his operation as a guarantee of authenticity. For when other arguments failed his opponents fell back on asserting that his descriptions of cases were falsified, and his record of results manipulated. He began life as a surgeon in the Royal Navy, and he was nearly forty years of age before he started work in London. When success did come it came with a rush, though indeed he had worked hard and strenuously to win it. He was in later years a great traveler, and his hale and cheerful appearance will be missed at many a medical gathering and at the autumn congresses.

I referred just now to the Victorian age. Next June the Queen will have reigned sixty years—the longest period in the history of this country for one monarch to sit on the throne. The event will of course be celebrated, but up to the present moment the Queen has resisted giving her consent to any one particular scheme to mark the event. Now however she has consented, indirectly, to allow the hospitals of London to gain the chief benefit of the celebration, by sanctioning an appeal in their favor from the Prince of Wales. This appeal is intended to reach many of those who have hitherto not subscribed to these great metropolitan charities, and so it is hoped that the large number of subscribers will compensate for the smallness of their donations. It is also intended that this fund will form a regular source of income for the London hospitals. It is satisfactory to note that in his appeal to the public the Prince has not overlooked "the fact that apart from the purely philanthropic work carried on in relief of the sick poor, we look to the voluntary hospitals for the means of medical education and the advancement of medical science."

It is curious that concentration of public attention on the hospitals should coincide with the work of the Hospital Reform Association, and with the suggestion of a Central Hospital Board for London. All three movements appear at the present moment to be in active progress, and there is good hope that in their several ways they will greatly benefit our hospitals, our schools, the public, and the profession.

Several successful cases have been published lately where ruptured gastric ulcer has

been treated by laparotomy, suture, and washing out of the peritoneum. The moment of rupture is generally well marked, and it has been found that the average duration of life after the occurrence is only twenty-four hours. Apart from the technical success of the operation, the most important factor is the promptitude with which the operation is undertaken. Once the diagnosis of rupture has been made every minute's delay rapidly diminishes the chance of success of the operation.

Some recent researches with regard to the presence of typhoid bacilli in the urine have possibly, if confirmed, great practical importance. From these researches it would appear that examination of the urine is of little value for diagnostic purposes, since the bacilli only occurred in it, when they did so occur, late in the disease; but the urine was often, though not in all cases, a serious source of infection, and should so be reckoned with. In one instance the bacilli persisted in the urine for twenty-two days after the temperature had fallen to normal.

If any one is interested to know what antiseptics have done for the lying-in woman, I would commend to his notice an address published in *The Lancet* of January 23. He will then not be surprised that the late Matthews Duncan dedicated his chief work to Joseph Lister as the man who had done more than any obstetrician to save life in childbirth.

We have had still another case in the law courts which may serve as a moral to medical men. A physician attended a child for what he considered to be "malignant sore throat." The child became seriously ill, and in their anxiety the parents suggested a consultation. To this the family attendant—an old friend—readily agreed, but before the consultant arrived the child died. On hearing from the parents an account of the illness the consultant said that the case must have been one of diphtheria. It was this unbalanced remark—for under the circumstances it could not be considered more than a mere guess—which led to the subsequent trouble. For two other children in the same family fell ill with diphtheria, and the father brought an action against his family attendant to recover the expenses he had been put to in connection with their illness, which he attributed to defendant's neglect in not enforcing suitable precautions from contagion on the occasion of the fatal illness of the first child. The defendant won his case by establishing that

the first case was one of malignant sore throat, and that he had in any case taken proper precautions in the way of isolation, etc. It was the hasty and ill-considered remark of the consultant, as the judge pointed out, which originated this painful case. It shows once again that none of us should hazard an opinion with regard to a case we have not ourselves observed, and that it is impossible to rediagnose a case when the case is over.

### PARIS LETTER.

By A. R. TURNER, M.D. (PARIS).

It may be said that the most well known physician in France at the present moment is Dr. Philippe Grenier, deputy of the Department of the Doubs. He is but thirty-two years old, and studied and graduated in medicine some years ago in Paris. Returning to his native town of Pontarlier he established himself in practice.

Some time afterwards Dr. Grenier declared that his studies of the Koran had brought him to the belief that Mohammedanism was the true religion. He consequently adopted not only the faith but the religious customs and even the external costume of the Arabs. Such conduct did not excite much comment in Pontarlier, a small town, where both Dr. Grenier and his family had long been known and esteemed for their honorable position.

It happened, however, that at the last election for deputy from the electoral district of Pontarlier Dr. Grenier presented himself as a candidate, and was elected. He sits on the left side of the Chamber of Deputies, and may be looked upon as half Socialist, half Radical, and in reality forming a party by himself.

Not only was interest in him aroused by the fact that a Mohammedan had been elected to the Chamber of Deputies, but by the exact fashion in which he carried out the principles of his new belief with reference to daily prayers and ablutions. Wherever he may be, in the Chamber of Deputies or in the streets of Paris, he goes through the required prayers when the hour has come.

The Chamber of Deputies in Paris is situated immediately opposite the river Seine. As a number of deputies had objected to the ablutions required by the Mohammedan law being performed in the dressing-rooms reserved for their use, Dr. Grenier would descend, when necessary, to the border of the Seine and there carry them out, pro-

tected from the larger crowd who would at once assemble, and who were even waiting for him, by a body of police.

Lately, however, a permanent official of the Chamber of Deputies, disgusted that a deputy should thus become the daily spectacle of Paris, offered the use of his residence in the Chamber to Dr. Grenier.

The costume which Dr. Grenier wears consists of a long Arab cloak and turban, worn over the usual European dress. In this he follows the custom of a former deputy, who having promised his electors to always appear in a blouse at the Chamber of Deputies, wore it over a frock coat.

Many of Dr. Grenier's political ideas are socialistic; others belong to him more especially as a Mohammedan. Thus he wishes to have all Mohammedans of Algeria and Tunisia declared French citizens, with all the rights of voting. His signature is: Doctor Philippe Grenier, Prophet of God.

Public opinion in France has been much excited over the possibility of the introduction of the plague into France from Bombay. All goods coming from the infected regions are now allowed to enter only at certain ports, where disinfection can be carried out. Recently a steamer running regularly between Paris and London was stopped below Paris, as on its manifest were borne several articles which originally came from the East. Though they had left India long before the presence there of any symptoms of plague, disinfection was insisted upon.

The population of Marseilles and its municipal government were even more excited than the remainder of France on account of the arrival direct from Bombay of two English steamers. Fears of a popular tumult were expressed in case they were allowed to land their cargoes. Telegrams were exchanged between Paris and Marseilles; the mayor of the latter city was writing letters of protestation, until finally the Central Government gave orders that the two boats should not be allowed to discharge their cargoes.

In connection with all this comic incidents occur. Some few days ago there arrived at the Swiss frontier, at Chiasso, in the train from Milan to Bâle, an Englishman locked into a sealed railway carriage. He was a traveler from Bombay who had landed at Brindisi. The station-master at Chiasso telegraphed for instructions to Berne, but obtaining no answer in time, returned the railway carriage to Milan, without allowing the passenger to leave it. The latter, it is reported, took the

affair very coolly, and gazed with a complacent air on the people outside, not seeming to suffer much from the plague-microbes he was supposed to carry with him. Finally, from later information, it seems that the passenger was eventually allowed to resume his journey for London.

Even were the plague to reach European countries, if treated with the serum manufactured at the Pasteur Institute the mortality should not be great.

At Amoy Dr. Yersin treated twenty-three cases by injections of serum, only two deaths occurring—one five hours and the other twenty-four hours after the injection. One of the two mortal cases was injected only on the fifth day of the disease, and the other was exceedingly serious. As the previous mortality in plague had been about eighty per cent. it may be said that the treatment by the serum was as successful as the treatment of diphtheria by antidiphtheritic serum.

The Pasteur Institute has at present about twenty horses immunized against the plague and ready to give serum.

A French writer, Dr. Leloutre, has recently given a method of self-ophthalmoscopy which may interest some. It may easily be carried out, according to the author, by means of an ophthalmoscope, a mirror, a lamp, and a lens.

A wardrobe with a mirror in the door, so often found in France, is the best to employ. Place yourself in front of the open door of the wardrobe, about twenty to thirty centimeters before the mirror, and at its edge. If you wish to examine the right eye place the lamp so that the light from it may be prevented by the mirror from striking the right side of the face. Hold the ophthalmoscope to the left eye, place the lens before the right eye, and throw the light upon the mirror in such a way that it will be reflected back upon the lens and into the fundus. The rest is only a matter of changing the position slightly until the desired result is obtained.

#### *ABSTRACTS FROM OBSERVATIONS MADE IN A DIPHTHERIA OUTBREAK.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: This outbreak occurred in November, 1896, in a country town in the northern part of Maine. It was my first battle with the disease, and it was my misfortune to lose two patients before its nature was recognized, as it presented itself in these cases in the form of suppurative tonsillitis, with distinct formation and discharge of pus, which gave relief

of all symptoms. There was no appearance of membrane upon either tonsils or uvula.

The patients were a lady thirty years of age and her daughter of about ten years. Both died of apparent sudden heart-failure, the mother's death occurring about six hours before that of her daughter, although she had not been sick as long as the latter.

The mode of death aroused my suspicion of malignant disease, and I called a consultant, but we were unable to make certain diagnosis until called to examine a throat in a neighboring family. This throat cleared up all doubts, as there was a distinct membrane already forming.

There was prompt quarantine of all affected and exposed, but only one other case developed that could possibly have come from that exposure.

Later two other cases appeared outside of quarantine, which also began with suppurative tonsillitis, but soon the membrane distinctly appeared, and with prompt isolation there was no spread of the disease.

Some two weeks afterward I was sent by the Board of Health to examine two families, and found both affected with diphtheria. Being large families there were consequently a number of cases.

No deaths occurred under my care after the disease was recognized, and all made good recoveries.

In every case I used antitoxin with excellent results and no bad effects. In nearly every case the membrane had separated within thirty-six hours after the first injection. A second injection was used only when there was not a distinct reaction within twelve hours.

I have used peroxide of hydrogen locally in the throat, and have given strychnine in heroic doses from beginning of disease and continued it through convalescence.

Without antitoxin I would be at a loss to treat a case of diphtheria satisfactorily, but with it I feel that I am using an absolute specific; for since November, 1896, I have seen and treated in this and surrounding towns twenty-seven cases without a death. I attribute the recovery in so many cases to the use of antitoxin. One of my fellow practitioners has not used antitoxin, and he has lost three cases out of seven treated.

As yet I have seen no bad effects from antitoxin, and I would recommend its use in all cases, whether seen early or late.

### TREATMENT OF CANCER OF THE RECTUM, WITH A REPORT OF TWENTY-FIVE CASES.\*

BY W. W. KEEN, M.D., LL.D.,

Professor of the Principles of Surgery and of Clinical Surgery,  
Jefferson Medical College, Philadelphia, Pa.

If you will pardon me for alluding to the diagnosis in a paper professedly considering only treatment, there are two points so important that I wish to say a very few words in reference to them. First, the dis-

ease often escapes the attention of the family physician simply because he fails to make an examination. Not long since I saw a gentleman with a very distinct cancer of the descending colon, discovered the moment that the hand touched the abdominal wall, yet it had been entirely overlooked by his physician simply because he had never examined the abdomen. One of the cases reported below had had positive symptoms of cancer of the rectum, including bloody stools, for two years, and yet his physician had never once made a rectal touch.

The second point is that in the digestive tract cancer is not necessarily confined to late middle life or old age. We are so accustomed

\* Read before the West Branch Medical Association, at Bellefonte, Pa., Jan. 12, 1897.

to take cancer of the breast as a type, in which organ cancer before the age of forty is rare, that we are in danger of considering the same rule as applying to other parts of the body. But in the digestive tract I have known several cases occurring before thirty, and recently Czerny (*Münch. Med. Woch.*, 1896, No. 11) has reported one case in a little girl of thirteen.

Turning now to the treatment of cancer of the rectum, this is divided into the *palliative* and the *radical*. The cases suited to palliative treatment are those in which the extent of the disease is too great to allow of radical treatment or the condition of the patient is such as to forbid extirpation of the disease. By the "extent of the disease," I do not mean chiefly the amount of the rectum involved, for that is only occasionally too great to allow of radical treatment. Whether the radical treatment can be done or not depends far more on the involvement of neighboring organs. If the bladder or the prostate in the male, or the posterior wall of the vagina and the lower part of the uterus in the female, are extensively involved in the disease, it will rarely be possible to effect a cure or even to obtain recovery after the radical treatment. Yet in one case operated upon by my colleague, Professor Montgomery, in which the entire posterior wall of the vagina and the lower part of the uterus were involved, he was able not only to remove the rectum, but also at the same time the uterus, ovaries, and the posterior wall of the vagina, and obtain a most satisfactory cure. Parts of the prostate and of the bladder in the male have also been removed with success, but ordinarily this cannot be hoped for. Usually cases in which these organs are involved would be best subjected to palliative treatment only.

*The Palliative Treatment.*—This consists in colostomy, in order to allow the feces to escape from an artificial anus and to avoid the damming up of the feces in the upper rectum and the colon, or, if there be not much obstruction, to avoid the passage of the feces over the ulcerated surface of the rectum. Either of these conditions, if not relieved, is productive of excessive pain and exhaustion, and, in the case of ulceration, there may be serious repeated hemorrhages.

Formerly our only resource was a lumbar colostomy. In my experience that is a most ineffectual operation. It is very difficult to produce an effective spur between the upper and lower parts of the opening which will

deflect all of the feces through the artificial anus. Almost invariably a small, and in some cases a very considerable, portion of the fecal material, instead of escaping from the artificial anus, continues its course into the bowel below the opening, making the artificial anus therefore to that extent useless. The only reason in former times for doing a lumbar colostomy was that we could operate without opening the peritoneum, a danger of the most serious character in pre-antiseptic days. Since, however, we have learned to deal with the peritoneum fearlessly by modern methods, there is no reason why lumbar colostomy should still be practiced. Besides, in some cases, the colon cannot be found, and the small intestine has been opened by error. I remember very vividly one case (No. XVII)—in which I did a lumbar colostomy about ten years ago—in which, to gain access to the colon, I was obliged to open the peritoneum and was in the greatest possible doubt for a considerable time as to which one of the two coils of intestine was the colon. I decided, fortunately, at last upon the right one. Had I opened the other, I should have created the artificial anus in the small intestine, which would have led to speedy death by inanition. From that time to the present, excepting in one case (No. XVIII), I have invariably done an inguinal colostomy, and for some years by Maydl's method.

As this method may not be familiar to all of you, I will briefly describe it. If we have reason to believe that the cancer has not extended so far up as to interfere with, or that within a reasonable time it will involve the opening to be made in, the bowel, the operation is done in the left inguinal region. If the cancer has invaded the sigmoid flexure, then the artificial anus is made in the right inguinal region, or if circumstances make it desirable, in the transverse colon.

An oblique incision is made in the left inguinal region, the centre of which lies just above the anterior superior spine of the ilium. The peritoneum having been opened, the finger is swept from the opening externally and then posteriorly along the belly wall, when, as pointed out by J. Chalmers Da Costa (*Medical News*, June 9, 1894, p. 634), the first coil of intestine met with must necessarily be the colon. If this maneuver be followed very little difficulty will be experienced in finding the colon. Ordinarily even this is unnecessary, for the colon will present itself at the wound or be found by the finger the

moment it enters the abdominal cavity. A loop of colon is then drawn out through the wound, and the upper colon is drawn down until all the slack is taken up. The object of this procedure is twofold: First, if the operation be a merely palliative one, by drawing down all of the slack we can to a great extent prevent or lessen the amount of subsequent prolapse of the bowel; secondly, if the radical operation is done later there will be less difficulty in drawing down the stump of the bowel. With a pair of hemostatic forceps the mesentery is perforated and a glass or other disinfected bar is passed through the opening. The bowel is now secured to the belly wall at the upper and lower ends of the incision by a transverse suture, so as to prevent any hernia resulting from efforts at vomiting, and the wound is then closed, excepting the central part where the loop of bowel protrudes. Sometimes I have sewed the parietal peritoneum to the skin so as to bring a large surface of peritoneum instead of the cut edges of the belly wall in contact with the bowel, and thus secure an earlier adhesion. How early this takes place is well illustrated in Case II. Five hours after the Maydl operation was completed, the patient complained of a great deal of pain from flatus owing to too sharp a kink of the colon over the glass bar, as I had not allowed quite sufficient slack of the bowel over that obstacle. Accordingly, as I had not in that case secured the bowel by any sutures, I seized the bowel with the finger and attempted to draw the upper portion down to a slight extent. The adhesions already existing between the intestine and the belly wall were so strong that it required considerable effort to loosen the bowel.

Instead of the glass bar which I ordinarily use, I have on two occasions passed a rope of iodoform gauze through the opening and secured it to the skin on each side by a stitch, so as to keep it taut. This answered the purpose perfectly. Another expedient I have also tried on two occasions with satisfaction (Cases XXI and XXII) is that suggested by Bidwell (*Lancet*, 1895, i, 753). Instead of the bar or rope one or two stitches are passed through the opening in the mesentery, and by means of the stitches the margins of the skin on each side are sewed together under the loop of bowel, the skin thus replacing the bar or gauze rope. Should the necessity for immediate opening of the bowel exist, as in the case of a child with an imperforate rectum, upon whom I operated forty-

five hours after birth, the bowel is then sutured all around to the skin by either an interrupted or better a continuous silk suture, when it may be opened fearlessly at once.

In dressing such a case, I soon found one little difficulty. If the gauze dressing is placed directly on the intestine, in a very short time after the operation the gauze becomes adherent to the bowel and is removed with some difficulty. To avoid this a small piece of disinfected rubber dam or oiled silk is placed over the bowel, and no such adhesions then take place. If the bowel is not to be opened at once, I have usually waited till the second or third or even till the fourth day, and then opened it either in the axis of the bowel or transversely, according to the need. If it is the intention that the opening in the colon shall only be temporary, the incision should be made longitudinally, so that it may be closed at a later operation. If the opening is intended to be permanent it is best to make a transverse incision; either then or later this is carried all the way down to the bar, rope, or skin, whichever method is employed, so as to cut the bowel entirely through. Usually one or more small vessels in the mesentery will spurt; these can be seized with hemostatic forceps and tied with silk. If there is any redundant bowel protruding, it may be resected to the level of the skin. All of this can be done without an anesthetic, as it causes little or no pain.

The ultimate result of a Maydl operation is most satisfactory. The patient can defecate either in the standing position or lying on the side. Usually a single or at most two movements of the bowels occur in the twenty-four hours, and meantime the patient is able to go about and attend to his ordinary occupations without the slightest inconvenience; no odor is perceptible, and the patient can enter into an active business and social life with perfect security. In Cases II and III this is notably the case. If diarrhea occurs, then there is apt to be trouble, and the patient is obliged either to remain indoors or to dress the wound much more frequently.

The mode of dressing such a wound is best described in the two cases just referred to. Some protrusion of the bowel occurs occasionally, but not to such an extent as to become a serious annoyance.

The advantages of a Maydl operation as a preliminary to the radical operation will be referred to later on.

Patients who are not amenable to a radical operation, and in whom the colostomy is done

merely for palliation, are rendered very much more comfortable and life becomes far more bearable. Its danger is very slight and its advantages very great. Incontinence being the exception rather than the rule, they can adjust their lives very readily to the varied conditions in which they find themselves. So comfortable have been several of my patients that they have been unwilling to submit themselves to a second operation for the closure of the artificial anus, being persuaded that they are more comfortable with the anus in a position where they can dress it personally than if they were to have an artificial anus at the end of the spine.

*The Radical Treatment.*—Until a few years ago no case was deemed suitable for radical operation unless the growth was within reach of the finger and was so limited as to require the removal of only a small portion of the rectum. This was still the prevailing opinion among the English surgeons so late as 1889. Mr. Allingham deprecated the removal of any growth, even four inches up the bowel, as unscientific and unsurgical, and Mr. Treves in his "Operative Surgery" states that the cases suited to excision are "comparatively few in number," and that "very rarely does the excised portion measure more than three inches in length. In no case should the peritoneum be deliberately opened." My own and many other reported cases show that these are by far too conservative views. We owe the extension of the modern radical treatment of cancer of the rectum chiefly to the enterprise and audacity of German surgeons. American and later English opinion (Ball, in Treves' "System of Surgery," ii, 787) seems to have recently undergone a rapid change in the direction of far more radical interference, so that it is now not uncommon to see cases reported in which six or eight or even ten and twelve inches of the rectum (Purcell, *Lancet*, 1896, i, 725) have been removed. Several of my cases illustrate extensive resections of six to nine and a half inches; in fact, these cases are more than a resection of the rectum; they involve a considerable portion of the sigmoid flexure of the colon. It may be stated, as a general rule, that all portions of the rectum and colon are now amenable to the radical treatment, if other conditions are not such as to forbid it. Those that are too low down to be reached by a celiotomy can be reached by the sacral method, and those too high up for the sacral method can be attacked by celiotomy. In fact the entire alimentary canal, except a

portion of the esophagus, is now accessible to the surgeon.

The radical treatment may be considered under two headings: first, the preliminary treatment; second, the actual resection or amputation of the rectum.\*

In the preliminary treatment the rectum must be thoroughly unloaded of its contents in all cases, which, if there is any obstruction of the bowel, are very considerable and may be enormous. Ordinarily surgeons lay down the rule that several days, amounting to a week or ten days in the opinion of some, are necessary for this preparation. My own experience leads me to believe that a much longer time is necessary to unload the bowels in the case of serious obstruction. For instance, in Case I a week was employed in unloading the rectum, and I supposed that it was reasonably empty, yet at the operation the field of operation and the towels and sheets around the patient were flooded with a continuous stream of fecal matter, which poured out for such a length of time that I was unwilling to prolong the cleansing of the bowel and terminated the operation without having effected a complete evacuation of the colon. In Case V seventeen days were employed in daily efforts, by moderate laxatives and repeated enemas, to cleanse the bowel, and yet it was found loaded with feces above the obstruction. The same condition has been found at operations by Schwartz after three weeks' preliminary attempts at complete evacuation, and by Kraske after a month. The accumulation has been so great that I have been compelled to believe that in some cases almost the entire colon was filled with fecal matter due to the obstruction. If such difficulty exists in emptying the bowel, how much more difficult will it be to disinfect it!

Whether a preliminary colostomy shall be done or not will depend chiefly on the amount of bowel to be removed. If we have good reason to believe that the cancer does not extend so high as to require the opening of the peritoneum, I should then be perfectly willing to forego a colostomy and trust to repeated efforts at unloading the bowel by moderate laxatives, covering not less than one week, and if necessary two or three. In administering these it is very necessary, however, to be watchful of the strength of the

\* Resection is the removal of a part of the rectum in its continuity, the anal portion being left. Amputation is the removal of the lower end of the rectum, including the anus.

patients. They are usually persons who have been very much exhausted by the continued pain and obstruction, and more or less by the auto-infection which has taken place, and if they are further weakened by active purgation they will be rendered unable to endure the operation. Usually, however, in cases where the cancer is low down, involving the third part of the rectum, this preliminary cleansing is sufficient without colostomy.

The great danger of all resections or amputations of the bowel, excluding primary shock and hemorrhage, is *infection*. If the peritoneum be not opened this danger is minimized, so that even should the wound become infected it will cause a local suppuration, but not peritonitis; hence this confessedly often imperfect method of cleansing the bowel may be sufficient in such cases. If, however, the cancer is situated more than three inches, or especially if more than four inches, above the anus, it is practically certain that the peritoneal cavity must be invaded. (Yet in Cases X and XIII I removed four and five inches without opening the peritoneum.) In all such cases I am, therefore, decidedly in favor of doing a preliminary colostomy for three reasons: first, it will greatly improve the general health; secondly, it will relieve the obstruction and consequently the pain; and thirdly, it enables us to disinfect the bowel far better than without a colostomy. By means of a catheter introduced into the inferior opening of the Maydl operation, the lower rectum can be washed out from above and the bowel not only cleansed of its fecal contents, but also to a large extent, though never completely, disinfected by a boric acid solution or a very weak bichloride solution, followed by a copious washing out with boiled water. But what is much more important, the contents of the bowel being deflected through the artificial anus, any later infection from soiling by feces is prevented. In women the vagina also should be well disinfected.

In resection or amputation of the rectum, if the anal portion and the anus itself is involved, then the rectum must be *amputated* at a point at least an inch above the growth. If an inch and a half or two inches above the anus are free, then it may be best to do a *resection* of the diseased portion and in some cases to reestablish the continuity of the bowel by methods to be discussed shortly.

The mode of access to the bowel has been entirely revolutionized by the efforts of Kocher, Kraske, and their followers. The

old operation through the perineum only allowed us to remove growths at or but little above the anus, but did not allow us to attack growths which were beyond or just within reach of the finger. Kocher took the first step toward the modern operation by the removal of the coccyx in 1874. This method was employed in Cases VIII and IX. In 1885 Kraske (*Arch. für Klin. Chir.*, xxxiii, 563) practiced a more radical operation by removing not only the coccyx but by chiseling off an oblique portion of the sacrum from opposite the left third sacral foramen to the lower left border. Since then his followers have increased the extent of the resection step by step, until Rose has even resected the sacrum transversely at its junction with the ilium. So extensive a resection of the sacrum, however, does not seem to be either necessary or desirable. A resection up to the third sacral foramen, being careful not to injure the third sacral nerve, should be the limit of operative interference with the bone, since if the third nerve is injured the innervation of the bladder is apt to suffer and incontinence of urine may result. I have never gone beyond that point, but have in several cases resected the sacrum transversely at that level, and have never seen the slightest trouble either from interference with the innervation of the bladder or trouble within the spinal canal itself, though in Cases II and V it was recognized that the spinal canal was opened. Not only can the rectum and part of the sigmoid flexure of the colon be resected through such an opening, but repeatedly the uterus and ovaries have been removed through the same opening.

I have always employed ether as the preferable general anesthetic, but in Cases XXII and XXIII I employed Schleich's fluid very successfully as a local anesthetic.

The operation is done as follows: The patient lies upon his side, whether upon the left or the right is, I think, a matter rather of the preference of the operator than otherwise. Those who are right-handed will, as a rule, find it more convenient to have the patient lie upon the right side. An incision is made from the posterior inferior spine of the ilium, curving toward the coccyx; it is then prolonged in the middle line nearly to the anus. If it is necessary to remove the lower part of the rectum, including the anus, then from the end of this incision two elliptical incisions are carried around the anus, one upon each side. If, however, the anal portion is to be preserved, the incision terminates just behind

the anal aperture. Sometimes I have found it desirable at the upper end to make an incision toward the right side in order to free the right side of the sacrum. The incision is carried directly to the bone, and the soft parts are rapidly dissected away from the bone till the edge of the sacrum and the sacro-sciatic ligaments are reached. These are divided and the soft parts separated from the left side of the coccyx and sacrum. The hemorrhage is apt to be quite free, but is arrested either by hemostatic forceps or by pressure with gauze sponges aided by hot water if necessary. But I usually waste little time on the hemorrhage until the soft parts are completely divided from the edge of the bones. Then the hemorrhage is arrested. The soft parts are then divided upon the other side of the sacrum and coccyx. With the finger, the Allis dissector, and a pair of blunt scissors curved on the flat, we now loosen the rectum from the anterior surface of the sacrum and coccyx, the tissues not readily loosened being cut either with the knife or the scissors. The hemostatic forceps or sponge pressure is then again required to arrest the hemorrhage. Commonly I pack with gauze sponges, and while the hemorrhage is being checked proceed to the resection of the sacrum. The middle sacral artery will require ligation. I do not usually chisel the sacrum as recommended by Kraske and others, but with a large pair of bone forceps I divide the sacrum transversely at the fourth sacral foramen if it is pretty clear that this will be high enough, or I resect directly at the third foramen. Occasionally when I have divided the bone at the fourth I have found it necessary later to take off a second piece with the forceps. Not uncommonly, as soon as the bone is resected, free hemorrhage takes place from its cut surface. Sometimes the vessels can be crushed between the jaws of the hemostatic forceps, but in any case in which the hemorrhage is troublesome, Horsley's putty will immediately arrest it.

Having laid bare the posterior portion of the rectum, we now proceed entirely to isolate it, first upon one side and then upon the other. This is best done by the finger or by blunt dissection. The inferior mesenteric arteries, one on each side, require careful ligation, as they are large vessels. Having separated it upon the two sides it must next be separated from the structures in front of it. Here considerable care must be used, especially in the male. In Cases III, V, and VIII, for instance, when this separation was

effected, the bulbous portion of the corpus spongiosum, the membranous urethra, the prostate and a portion of the bladder were all in sight. In order to avoid danger, especially to the urethra, it is generally wise to insert a bougie in order to warn us of the near presence of the urethra, prostate, and bladder; this is particularly needful if the adhesions of the growth are at all marked. In women the connective tissue between the rectum and the vagina enables us to separate the rectum from the posterior wall of the vagina with relative ease if it be not involved, but very often the growth has involved this tissue and may make the rectum very adherent to the vagina. As already stated, if the wall of the vagina itself is extensively involved, as a general rule it would seem wiser to forego any operation—a rule, however, which the case of Montgomery proves not to be absolute. If the vagina be only moderately involved, as in Case VI, a V-shaped portion, including all the diseased tissue, should be removed and the incision closed by sutures.

Having isolated the rectum at the lower portion, it must be freed upward beyond the growth. Traction will bring a large portion and perhaps the whole growth well into view. In freeing the rectum higher up, care must be taken in two directions: first, that the meso-rectum, when we reach it, shall be divided in such a way as not to interfere with the vascular supply lest the stump should undergo necrosis; second, especially upon the two sides and in front the danger exists of opening the peritoneum. If this can be avoided it is far better to do so, as it diminishes greatly the danger of septic peritonitis. If the growth extends high up, however, it will be necessary to open the peritoneum, and this should then be done purposely. Once it has been opened the bowel should be drawn down far enough to clear the growth by at least an inch and a half or two inches. As soon as the rectum is drawn down to this extent the opening in the peritoneum should be immediately closed by suturing its border to the anterior surface of the rectum. This brings peritoneum in contact with peritoneum and insures an almost immediate closure of the opening in the peritoneum, and so avoids a septic peritonitis. Careful search should now be made for any glands which may be diseased. They lie posterior to the rectum. Every gland which is discovered should be removed.

In all the manipulations to this time it is of great importance if possible not to have

opened the rectum. Sometimes it is so friable from the growth that this cannot be avoided, but where possible it will be easily seen that if we can avoid opening the rectum until after we have closed the peritoneal cavity the danger of septic infection is vastly less. I cannot at all agree with McCosh (*New York Medical Journal*, Sept. 3, 1892), who advises that if the peritoneal cavity has been opened, no attempt be made to close it, but that we shall rely upon packing with iodoform gauze. Suturing as I have described it can be done easily and accurately, and it will protect the peritoneal cavity from a possibly fatal infection far better than by packing with iodoform gauze. The bowel is now divided at a point at least an inch above the growth, the stump being seized with hemostatic forceps, which can be placed at points which will control the arteries, of which there are usually several that bleed. The diseased portion of the rectum is then drawn out and either the entire lower part is amputated or such portion of it is resected as is necessary. If it is perfectly clear from the beginning that an amputation rather than a resection of the rectum must be done, then it is desirable, I think, to begin from the anal end and work upward. Whether we shall work upward or downward will depend upon the exigencies of each case. Campenon (*Centralblatt für Chirurgie*, 1895, 272), Rehn (*Wiener klin. Woch.*, 1894, 249), Byford (*Annals of Surgery*, November, 1896, 631), and Bristow (*Medical News*, Dec. 5, 1896) have also attacked the cancerous rectum through the vagina. Maunsell of Australia (*American Journal of the Medical Sciences*, March, 1892, 245) proposed a new and ingenious method of intestinal anastomosis by invagination through a temporary opening which has been applied to the upper rectum by Hartley (*New York Medical Journal*, Oct. 22, 1892, 464), of which the simple model I show you will give a clear idea. It is only applicable to a few cases of limited growths high up in the rectum or in the adjacent sigmoid flexure, but is there a most valuable method.

As an addendum to the consideration of Kraske's operation for cancer, I may add that it has been utilized in syphilitic stricture of the rectum by Herczl (*Annals of Surgery*, September, 1892, 267) and lately by Higgins (*Boston Medical and Surgical Journal*, May 14, 1896, 485), Elliot (*Medical News*, Oct. 17, 1896, 436), and a few days ago by myself in operating for imperforate rectum.

*Temporary Resection.*—The methods spoken

of thus far have all comprehended the entire removal of a portion of the sacrum and all of the coccyx. A half-dozen different methods have been devised by which the sacrum and coccyx are divided longitudinally, transversely, or obliquely, without separating the flaps of skin from the bone. In other words, an osteoplastic resection, such as we often do in the skull, is made. The advantages claimed for this method are: first, that it restores the integrity of the bones; second, that in women who are operated on before the termination of their child-bearing period the integrity of the pelvic planes is restored by not disturbing the sacro-sciatic ligaments. Sieur (*Arch. Prov. de Chir.*, June, 1896, 333) states that there is but a single case reported (Lihotsky, published by Hochenegg, *Wiener klin. Woch.*, 1889, No. 30) of a woman successfully giving birth to a child after such an operation. Morenstein (quoted by Gerster, *Transactions of the American Surgical Association*, 1895, xiii, 93) narrates, however, a second in which, while the parturition was normal, the woman died of infection from a sacral fistula through the hand of the accoucheur. The birth being normal in both cases, this object seems to me to be of very small moment. I cannot see also the importance or necessity of replacing the temporarily removed sacrum and coccyx. In all the cases in which I have operated that have survived, there has not been a single complaint of inconvenience from the loss of the coccyx and part of the sacrum. Indeed in Case II the restoration to function of the perineum and bones of the pelvis is such that he rides a bicycle, and in Case III the same diversion has been begun, four years after the operation. I cannot, therefore, think that it is important that the bones should be replaced, and it certainly adds to the danger. Union of the bones is not by any means so readily obtained as union of the soft parts, and if the replaced bone becomes infected or necrotic, it adds not a little in my opinion to the danger. I have, therefore, always removed the bone entirely.

*Treatment of the Bowel after Amputation.*—

If the lower end of the rectum has been amputated the only question is, What shall be done with the upper end? I have in most instances simply attached it to the lower end of the resected spine. If no artificial anus has been made, it is essential that the resected end shall fulfil hereafter the function of the anus. We can almost always bring it down to the end of the spine, and I have never had any difficulty in attaching it there.

The objection, of course, to this method is that there being no sphincter, the patient has no control over his motions. This is by no means always the case, though unfortunately it is apt to be one of the disagreeable sequels of such an amputation. To avoid this absence of sphincter Gersuny (*Centralblatt für Chirurgie*, 1893, No. 26) proposed that the end of the bowel should be seized by two forceps and twisted a half or even a whole revolution so as to make an artificial sphincter by the twist. I have twice resorted to this method (Cases VIII and XIII) and have regretted it in each instance. I have not been able to secure the twisted and puckered end of the bowel to the adjacent soft parts so that infection did not take place between the sutures; and though the patients recovered, yet practically the method was worth nothing, or rather was worse than worthless, since it led to the infection. Gerster, Marcy and others, however, have had more success and approve of the method. Willems (*Centralblatt für Chirurgie*, 1893, No. 19) has tried to meet the difficulty in another way by carrying the end of the bowel through the fibres of the great gluteal muscle just as in a gastrostomy we utilize the fibres of the rectus so as to make them serve as a sphincter. I have never tried this method.

In case an artificial anus has been made in the colon as a preliminary operation to the radical extirpation, in thinking over the matter I am inclined in my next case to close the lower end of the bowel at the point of section, leaving the artificial anus to serve not only for the escape of the feces from above, but also as an outlet for the small amount of mucus that will gather in the rectum below the artificial anus. In fact, in view of the remarkable results obtained by Obalinski, Eiselsberg, Luhrs (*Centralblatt für Chirurgie*, 1896, 809, 830 and 1007) and others from total exclusion or closure of a large part of the bowel about the caput coli, I have contemplated even the possibility of closing both ends of that part of the rectum below the Maydl operation.

#### *Treatment of the Bowel after Resection.*—

If sufficient of the anal portion of the rectum is healthy it may be preserved, thus preserving the sphincter intact. Though in the majority of cases this will not be possible, yet in a few it may do very well. In that case the attempt should be made if possible to restore the continuity of the bowel so as to obtain the advantage of the normal sphincter. Circular suture of the two ends has been tried

repeatedly, but unfortunately fails from tearing out of the stitches owing largely to the amount of traction upon them; and this giving way of the stitches is followed by infection of the wound or by a fecal fistula. The use of Murphy's button for uniting the two ends has been practiced very rarely and not very successfully. I have tried it but twice. In Case I a septic peritonitis carried off my patient as a result of the secondary operation in which I used the button thirteen months after the first operation. In Case XV the button also proved fatal from sloughing of the bowel. Hochenegg (*Wiener klin. Woch.*, 1889, No. 30) has proposed to solve the difficulty in an ingenious way which my colleague, Professor Montgomery, resorted to some time since in a case, but with an unfortunate result. He seizes the upper end, draws it through the anal end, and attaches the upper end to the skin around the anus. To facilitate adhesion of the upper end to the inner surface of the anal portion the latter would best be deprived of its mucous membrane by thorough curetting or by the scissors. The sutures of course always tear out, but before they have torn out the adhesions are sufficiently strong in some cases to hold the bowel approximately at least in place, and restores the continuity of the lower portion of the digestive tube. If this—which I think is the best solution of the problem—cannot be done, then I prefer to remove the lower portion entirely and attach the end of the rectum to the resected spine or close it as I have above suggested.

The results should be considered in three aspects: First, as to immediate mortality; second, as to ultimate cure; third, as to comfort after the operation.

First, *the immediate or primary mortality.*—Sieur (*loc. cit.*) states that the mortality reported by Iversen in 1890 was 57 per cent.; Schede, 25 per cent.; Czerny, 19 per cent.; Albert, 10.9 per cent. Sieur collected in France 95 operations with 37 deaths, a mortality of 38.9 per cent. Of the 37 who died, 11 died from hemorrhage and shock and 18 from septic infection, leaving 8 from other causes.

McCosh in 1892 (*New York Medical Journal*, Sept. 3) collected from seventeen different authors, all German surgeons, excepting Cripps in England (thirty cases) and Kelsey in America (seven cases), a total of 439 cases with 84 deaths, a mortality of 19.1 per cent, which may be taken to represent the average mortality at that time, and probably it is not far from that at present. The mortality of

my own cases of extirpation (I–XV) is 20 per cent.

Secondly, *the ultimate cures*.—McCosh collected from one English and nine German surgeons 375 operations, of whom thirty-two were perfectly well at the end of four years, the limit usually assumed as assuring a permanent cure, to which should be added a certain number of the 375 cases which had not yet reached the four-year limit, some of whom undoubtedly would be permanently cured. Eleven or twelve per cent., therefore, at that time was an approximately correct proportion of absolute cures. I believe it will be found much greater as time goes on.

Of my own fifteen extirpations twelve survived, and four have reached or passed the four-year limit, giving a present percentage of  $33\frac{1}{3}$  per cent. of permanent cures, and Case XIII has nearly reached the three-year limit without return. Case XIV may survive to or beyond the four-year limit. Had Case I not been operated upon the second time he might have been as fortunate. These cases would still further increase the percentage of recoveries. Even where cure is not effected, just as in cancer of the breast, life is very much longer than is the case after a simple colostomy; probably on the average by eighteen months. It must not be forgotten also that in some cases where a relapse has followed, a second or even a third operation has resulted in permanent cure.

Thirdly, *as to comfort after operation*.—As compared with the damming up of the feces, with its alternate diarrhea and constipation and its dreadful pain, incontinence is preferable. Moreover, a large proportion of the patients do not suffer from incontinence, excepting when they have diarrhea, and if an artificial anus is made after Maydl's method, as several of my patients prove, the comfort is almost absolute. Case II is a gentleman in the first social position, who has traveled along the shores of the Mediterranean and in various social centres of Europe, mingling freely with his friends and acquaintances without many of them even knowing that he has ever had such an operation. He rides a bicycle and is in every respect restored to his normal life.

Case III is another instance of equally perfect restoration to the activities of life. He is a merchant in a neighboring city and comes to Philadelphia in the morning, goes among his business friends making his pur-

chases and attending to his usual business as if nothing had ever happened; and many of his acquaintances also are not aware that he has ever had an operation performed.

The first of these cases is now two months past the four-year limit, the other has just reached the four-year limit.

Case IV, after four years, is hale and hearty and is almost as comfortable as the other two.

Case XI also was able to enjoy an active business life for nearly all of the four years he survived the amputation of the rectum, and died of an intercurrent affection.

Case XIII for two years and ten months has been most comfortable and has no incontinence.

Case I for the year that he lived was able to resume his duties as a clergyman with comfort.

*Contraindications to Operation*.—I have already referred to the principal contraindications, namely, such extensive adhesions to neighboring organs and their involvement by the cancerous growth that it would be better simply to do a palliative colostomy, and disease too extensive to allow of removal. Besides these, however, there are other contraindications which should not be forgotten which exist in connection with the general state of the patient—e.g., if the patient is too old or is too feeble to withstand the serious shock of a resection or amputation of the rectum (as in Cases XIX, XXII and XXIII). I have never been able to accomplish the operation in less than an hour and a quarter, and sometimes even two hours. In very rare cases somewhat more time may be required to do it. Such an operation, therefore, is a very serious shock and must not be undertaken in persons of such age or general health that they could not withstand it. The general condition of the organs of the chest and abdomen should be considered. Cases of pulmonary trouble, especially of emphysema and bronchitis, should not be operated on if we can spare a reasonable time for the purpose of relieving them of the pulmonary complications. I need not call attention, I am sure, to the necessity of examining the abdominal organs, especially the kidneys, for evidences of Bright's disease or pyelitis, and also all the abdominal organs for possible secondary deposits of cancer, especially in the liver. In women also the breasts, uterus and ovaries should be examined, for if cancer exists in other organs besides the rectum, no prudent surgeon would think of doing an

operation. In case the general health has been broken down by pain, especially the pain caused by rectal obstruction, a patient whose rectum cannot be operated on to-day can occasionally be put in good condition for a later operation by making an inguinal anus to relieve the discomfort and pain. This relief is sometimes so marked that the patient's appetite, sleep and general health improve astonishingly in the course of a few weeks and make a later operation possible. To illustrate the above remarks the following reports are taken from my case-book:

The mortality of the twenty-five cases recorded below is as follows:

**SERIES 1.—EXTIRPATION BY KRASKE'S OR KOCHER'S METHOD.**

Case I recovered from the operation, but died from septic infection thirteen months later on attempt to reestablish the continuity of the bowel.

Case II survived the operation four years and two months, and had no recurrence during that time.

Case III survived the operation four years, and had no recurrence.

Case IV survived four years and one month, with no recurrence.

Case V recovered; no later history.

Case VI died from shock thirteen hours after operation.

Case VII died from uremia fifty-six hours after operation.

Case VIII recovered; no later history.

Case IX recovered; no later history.

**SERIES 2.—EXTIRPATION BY THE PERINEAL ROUTE.**

Case X recovered from operation; no later history.

Case XI died four years later from acute diarrhea; no return up to that time.

Case XII recovered; no later history.

Case XIII has survived for two years and ten months without recurrence.

Case XIV is still living, after ten months.

**SERIES 3.—EXTIRPATION BY CELIOTOMY AND USE OF MURPHY'S BUTTON.**

Case XV died from sloughing of the bowel on the third day after operation.

**SERIES 4.—INOPERABLE CASES IN WHICH LUMBAR COLOSTOMY ONLY WAS DONE.**

Case XVI recovered from the operation, but died about two years later.

Case XVII died about one year after operation.

Case XVIII died from acute entero-colitis twenty-four days after operation.

**SERIES 5.—INOPERABLE CASES IN WHICH INGUINAL COLOSTOMY (MAYDL'S METHOD) WAS DONE.**

Case XIX recovered from operation, but died from exhaustion thirty-one days later.

Case XX also died from exhaustion fifteen days after operation.

Case XXI died on the fifth day from exhaustion.

Case XXII recovered; no later history.

Case XXIII died from gangrene of foot resulting from femoral thrombosis thirty-seven days after operation.

Case XXIV died from exhaustion two months after operation.

Case XXV died from exhaustion after surviving the operation nearly three years.

**SUMMARY.**

Grouping together the various series, it will be seen that in the first three there were fifteen cases in which the growth was extirpated. Of these fifteen, twelve recovered and three died from shock, uremia and sloughing of the bowel respectively.

Of five of the twelve cases, no later history has been obtainable.

Of the other seven, one is living after four years and two months without recurrence; one is living after four years and one month without recurrence; one is living after four years without recurrence; one lived four years and died without recurrence; one is living after two years and ten months without recurrence; one died thirteen months later from septic infection after a second operation; one is living after ten months without recurrence.

This gives at least  $33\frac{1}{3}$  per cent. of definite cures (four year limit) in the twelve operative recoveries.

Of Series 4 and 5, the inoperable cases in which a lumbar or an inguinal colostomy was done, there were ten cases, of which nine recovered and one died on the fifth day from exhaustion.

Of the nine who recovered, the ultimate history of eight is known: One lived nearly three years; one lived about two years; one lived about one year; and five died in periods of from fifteen days to two months.

Of the whole twenty-five cases, twenty-one made a recovery from the operation and four died, a mortality of sixteen per cent.

THE RELATIVE VALUE OF DIGITALIS IN  
ORGANIC VALVULAR DISEASE  
OF THE HEART IN  
CHILDREN.

BY H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica, Jefferson  
Medical College, Philadelphia.

In the treatment of cardiac valvular disease with failure of compensation in children the writer of this article has found that in a certain proportion of cases the use of digitalis does not produce the good effects usually met with when it is given to adults, and he first called attention to this fact and to the value of strophanthus as a substitute for digitalis in children in a short article contributed years ago to the *University Medical Magazine*. While he is not to be understood as doubting the usefulness of digitalis in the heart lesions of children, he believes that it must be given even more guardedly than in the case of the adult, and not commonly fails to do good. This failure seems to depend upon the fact that cardiac arrhythmia develops and signs of auricular distention appear as soon as enough digitalis is given to maintain the improvement desired. To such an extent has this been the case that I have almost entirely given up the use of digitalis in persons under puberty, and resort to strophanthus in heart lesions and alcohol in heart failure resulting from the fevers such as pneumonia. With the object of determining whether other clinicians had reached similar conclusions I sent the following questions to a number of well known physicians interested in pediatrics, and have received the following replies:

1. Have you found that digitalis is as useful a drug in the treatment of cardiac valvular affections in childhood as it is in the same disease in adults?

2. If so, have you noticed that any particular variation in dose or in frequency of administration from that used in adults is necessary to produce good effects?

3. If not, what has been the apparent cause of its failure and what disagreeable symptoms has it caused?

4. What cardiac tonic or stimulants have you found most useful in this class of cases in place of digitalis?

5. Has strophanthus done well in your hands in such patients?

These questions were sent to Dr. L. Emmett Holt, Professor of Diseases of Children in the New York Polyclinic; Dr. J. P. Crozer

Griffith, Clinical Professor of Diseases of Children in the University of Pennsylvania; Dr. W. C. Hollopeter, Professor of Diseases of Children in the Medico-Chirurgical College of Philadelphia; Dr. Abraham Jacobi, Clinical Professor of Diseases of Children in the Medical Department of Columbia College; Dr. J. Lewis Smith, Emeritus Professor of Diseases of Children in Bellevue Hospital Medical College; Dr. Reynold W. Wilcox, Professor of Therapeutics in the New York Post-Graduate Medical School; Dr. Frederick Forchheimer, Professor of Diseases of Children in the Medical College of Ohio; Dr. E. E. Graham, Clinical Professor of Diseases of Children in the Jefferson Medical College of Philadelphia.

The answers to Question 1—Have you found that digitalis is as useful a drug in the treatment of cardiac valvular affections in childhood as it is in the same disease in adults?—are as follows:

Dr. L. Emmett Holt thinks digitalis as useful as in adults.

Dr. Griffith agrees with him.

Dr. Hollopeter does not find it as useful.

Dr. Jacobi thinks that children bear digitalis better than do adults.

Dr. Graham replies: "A very useful drug; applicable to more cases than any other one drug; is as useful in children as in adults."

Dr. J. Lewis Smith evidently finds digitalis useful in the heart disease of children, for he says: "I believe it is efficient and safe when given to children over the age of five to six years, but it should not be given oftener than six or eight hours. To children of eight years the dose of the infusion is a teaspoonful, which should be discontinued or given less frequently when the characteristic symptoms begin to occur. Six or eight drops of the tincture may be given in place of the infusion and with an alcoholic stimulant or camphor." Dr. Smith believes that it is a matter of the greatest importance to obtain a leaf of the best quality, and its efficiency is probably most certain when it is given in infusion.

Dr. Wilcox answers us that he has not found it so useful.

Dr. Forchheimer answers "Yes," and adds: "My views as to digitalis in children can be tersely expressed as follows: that it is well borne by them; that the dose, if anything, can be made larger in proportion than in the adult; and that it should *never* be given when compensation is not disturbed. In the disregard of the latter I have found the source

of conflicting statements regarding the utility of digitalis in children as well as in adults."

In answer to Question 2—If so, have you noticed that any particular variation in dose or in frequency of administration from that used in adults is necessary to produce good effects?—

Dr. Holt thinks the use should be rather smaller than of most drugs for the same age.

Dr. Griffith replies that he thinks that children bear it very well. He recommends the same proportionate dose at the same intervals.

Dr. Hollopeter says children will not tolerate digitalis long enough to accomplish any good from its use. He thinks the infusion the most desirable preparation.

Dr. Jacobi uses the infusion, fluid extract, solid extract, and digitalin.

Dr. Graham says: "Best given four times daily; have given it continually for weeks without noticing any ill effects. The same dose does not always produce the same result. I believe this to be due as much to variations in the strength of the drug as to personal idiosyncrasy."

Dr. J. Lewis Smith says: "I think not; similar ill effects may occur in children and in adults. The most common is nausea or a sensation of depression, which may be relieved by alcoholic stimulation or by camphor."

Dr. Wilcox thinks the dose should be smaller than that calculated from age.

Dr. Forchheimer answers, No.

In answer to Question 3—If not, what has been the apparent cause of its failure and what disagreeable symptoms has it caused?—

Dr. Holt has seen no disagreeable symptoms unless excessive doses were used for a prolonged period.

Dr. Griffith does not answer this question.

Dr. Hollopeter says it causes nausea and vomiting if continued for any length of time.

Dr. Graham says: "Digitalis fails to do good in cases of degeneration of heart muscle as in the infectious diseases, in irregularity of heart's action due to nervous excitement in early stage of acute endocarditis."

Dr. Wilcox says the cause is probably due to excessive vasoconstrictor action in children. Its use is limited to rapid irregular pulse and morbid mental nervous congestion irrespective of valvular lesion.

Dr. Forchheimer believes its failures to lie in "mistakes in accurate diagnosis."

To Question 4—What cardiac tonic or

stimulants have you found most useful in this class of cases in place of digitalis?—

Dr. Holt has usually combined strychnine with digitalis or used strychnine alone, but does not think it can replace digitalis.

Dr. Griffith has used digitalis chiefly and cannot compare with others, unless strychnine is included, which he has found extremely useful.

Dr. Hollopeter says: "Strychnine, which should be given in the same doses as in the adult (unfortunately the adult dose is only a child's dose), sparteine sulphate, and caffeine citrate." All of these are preferable in his opinion to digitalis.

Dr. Jacobi believes that tincture of strophanthus in the dose of six to twenty-five minims is useful.

Dr. Graham says: "Alcohol in degeneration of heart muscle and infectious diseases, opium and veratrum viride in early acute endocarditis, rest and bromide in nervous excitement."

Dr. J. Lewis Smith replies: I give nuxvomica guardedly and cautiously, or strychnine. I prefer, however, the following treatment for a child of eight years if digitalis fails:

Tincturæ ferri chloridi, f 3 ij;

Syrup ananassa sativa (pineapple), f 3 v.

One teaspoonful every three hours, alternating with:

Spt. æther nitrosi, f 3 ss;

Spt. Mindererus, f 3 iv.

One teaspoonful every three hours.

Dr. Wilcox answers strophanthus and to a less degree sparteine.

Dr. Forchheimer answers strophanthus and strychnine.

To Question 5—Has strophanthus done well in your hands in such patients?—

Dr. Holt thinks strophanthus decidedly inferior to digitalis.

Dr. Griffith has used it little or not at all.

Dr. Hollopeter used strophanthus for years only with disappointment. He has no faith in it.

Dr. Jacobi evidently, from what he says, places it next to digitalis.

Dr. Graham says: "It is a good drug to replace digitalis, but less efficient."

Dr. J. Lewis Smith says: "No, but perhaps a poor quality has been used."

Dr. Wilcox says "Yes."

Dr. Forchheimer has proved strophanthus to act well.

In connection with these reports it is interesting to note the opinion of a number of

well known authors on this subject. In many cases no definite comparative statement is made.

Carmichael says: "As to drugs, iron and digitalis take the first rank. My experience of strophanthus in children is very favorable; in many cases I prefer it to digitalis; it acts more rapidly and is not so liable to produce sickness, and has no cumulative effects." In regard to dilated heart Carmichael says: "Digitalis is also of much service, but probably in a less degree than strophanthus. I have had the best results from this remedy in such cases. It is a pure cardiac tonic, with little or no action on the blood-vessels, as is the case with digitalis. I am in the habit of giving it every eight hours in doses of five to ten drops, in children from six to ten years old."

On the other hand Donkin says, in speaking of acute cardiac disease: "I say nothing special of strophanthus and convallaria, which I seldom use now; for I have found the sickness which digitalis is often accused of causing very rare, if not mythical."

The conclusions then to be drawn from this collection of individual opinions seems to be in favor of digitalis as a cardiac tonic in the valvular cardiac diseases of children, although I still believe that its use should be cautious and that cases will be more frequently met with in which that drug will fail to act satisfactorily than in the adult.

#### *CHELIDONIUM MAJUS IN THE TREATMENT OF CANCER.\**

By C. D. SPIVAK, M.D.,

Assistant in Medicine and Lecturer on Diseases of the Stomach and Intestines in the Medical Department, University of Denver.

In the *Vratch* of July 25, 1896, there appeared a communication from Dr. Denissenko, chief of the City Hospital of Bryansk, in which he made the statement that for some time past he has treated all cases of inoperable cancer with *Chelidonium majus*, and that he had obtained encouraging results. He described in detail the methods he used, and begged his colleagues to take up the subject and give the drug a thorough trial. The communication, which was written in an unassuming manner, bearing rather the form of a prayer to his brother practitioners to sustain him in his labors, and the fact that the article

was published in the *Vratch*, one of the best medical journals of the world, made his words carry with them the conviction that, at all events, the man is honest even if he errs, and that he by no means seeks notoriety. The news spread like wild-fire, and the medical press of the world gave the item more or less notice. It has even penetrated into the columns of the daily press. Since that time many prominent physicians and surgeons in Russia, Germany and France have experimented with the drug, and communicated their results in the various journals.

I have the honor to present to you a summary of the literature on the subject up to date.

A few words about the drug from a pharmaceutical standpoint. Its synonyms are: Chelidonium, Celandine; Herba Chelidonii, P. G.; Tetterwort, E.; Chélidoine, Herbe à l'hirondelle, Fr.; Schoellkraut, G.; Borodavnik, Chistotyel, Russ.

*Description.*—*Chelidonium majus*, Lin., Natural Order Papaveraceæ, is a perennial herb indigenous to Europe, and introduced on this continent. It grows about old houses, waste and rocky places. It is one or two feet high, bears pinnate leaves and small peduncled umbels of yellow flowers, and when wounded emits a yellow opaque juice of a milky consistence, unpleasant odor, and a pungent, acrid taste. It contains besides various extractives and tar-products, chelidonic and chelidoninic acids, two alkaline principles—chelidone and chelerythrine—and a neutral crystallizable principle, chelidoxanthine. Dr. James Schiels of St. Louis has found chelerythrine to be identical with sanguinarine. Selle (*Archiv der Pharmacie*, 1890) has found three other alkaloids, which he named respectively  $\alpha$ -Homochelidone,  $\beta$ -Homochelidone, and Protopine.

Tetterwort has been used in folk-medicine for centuries in the form of poultices, infusions, and as the juice. The medical men of some 150 years ago used it in various ailments—scrofulosis, syphilis, eye and skin diseases. It was considered a specific in jaundice and all liver troubles, and is known as *Decoctum ad ictericum* of the Edinburgh Pharmacopœia. The fresh juice is a popular remedy for warts and corns. It is also used as a remedy in phthisis.

*Physiological Action.*—Introduced hypodermically into a frog, it produces a semi-narcotic state, the reflexes are weakened, the peripheral sense-nerves are dulled, the irritability of the spinal nerves is lowered. Both

\* Read before the Denver and Arapahoe Medical Society, March 9, 1897.

the motor and inhibitory centres of the heart become paralyzed. The muscles show no change.

Introduced hypodermically into warm-blooded animals, it produces local irritation, and the temperature rises one or two degrees. Blood-tension is lowered by one-half. Respiration is markedly affected and becomes quicker and deeper. A lethal dose, producing paralysis of respiration, is 0.1 to 0.2 to the pound of body weight.

The microscopic examination of tissues into which chelidonium was introduced hypodermically revealed that the outlines of the individual epithelia become more distinct, the cells smaller, and the protoplasm cloudy.

An aqueous extract is used which should possess the following properties: homogeneous liquid, greenish-gray or greenish-brown color, of oily consistence, somewhat acid to taste, and possessing a pleasant odor.

Administered internally the dose is 1.5 in peppermint-water, to be increased to 5.0 in twenty-four hours. When administered externally the parts to be treated are covered with antiseptic gauze saturated in a solution of the extract of chelidonium and distilled water (2 to 1), to be applied once or twice daily. In hypodermic administrations equal parts of chelidonium and distilled water should be used, not more than 1.0 of the solution at a time, and not oftener than once a week.

Its effects are shown after five to seven days of internal medication, in the disappearance of the sallow hue of the skin; the appetite improves, pain is mitigated, the urine is increased in quantity. In from two to three weeks the tumor becomes softer and smooth and diminishes in size.

The external application, wherever the tumor is accessible to such treatment, hastens the process of recovery. It does not affect in any way the healthy tissue, and does not interfere with granulation.

The hypodermic medication was at first administered into the parenchyma of the new growth, but such procedure having in a few cases caused a severe reaction to follow—chill, rise of temperature, acceleration of pulse and fainting spells, which however passed away in from two to five hours—it was therefore abandoned, and the injections are made into the healthy tissue a short distance from the boundary of the neoplasm, which is not followed by any reaction at all. In a few days softening of the tumor sets in; in from fifteen to twenty days a line of

demarcation can be distinguished between the morbid and the healthy tissue; the one seems to be forced away from the other, and the whole tumor can sometimes be easily pressed out. In general, the tumor diminishes more than one-half in circumference, and the affected lymphatic glands of the neighborhood undergo involution.

The following cases have been described in literature:

Denissenko: I.—Forty-eight year old male; epithelioma of the lower lip; external application; hypodermic injections twice; cicatrization in forty days. II.—Tumor of lower lip, nature not known, probably epithelioma; hypodermic injection once, drug taken internally daily; cure in thirty days. III.—Fifty-three year old male; carcinoma of the bridge of the nose; four injections; daily applications; cicatrization in one month. IV and V.—Cancer of the esophagus; internal treatment for two months; recovery. VI.—Fifty-four year old male; cancer of the anterior wall of the stomach; internal treatment for ten weeks; no pain; increased in weight; returned to his vocation. VII.—Cancerous tumor on right side of neck; condition of patient pitiable; sick for one and a half years; internal and hypodermic treatment for two months; tumor decreased in size; general health greatly improved.

Zelenski: VIII.—Patient, male, eighty-five years old; for fifteen years suffered from a cancerous growth in left meatus of ear; two hypodermic injections were given, internal and external applications,—all at the same time; half an hour after, severe chills, vomiting, fainting, rise of temperature. Treatment abandoned.

Berezkin: IX.—Cancer of breast, internal; external and hypodermic treatment for two months; no improvement. X.—Cutaneous cancer on back for two years; treatment for one month; no improvement. XI.—Cancer of glands of neck; patient after first injection refused further treatment. XII.—Cancer of parotid gland; no improvement. XIII.—Cancer of tongue; two months' treatment; no improvement. XIV, XV, XVI, and XVII.—Cancer of uterus; no improvement. XVIII.—A case of warty growth; external application eighteen times; no improvement.

Pomerantzeo: XIX.—Cancer of breast; no improvement. XX.—Cancer of inner canthus of eye; no improvement. XXI.—Cancer of lower jaw; no improvement. Duration and mode of treatment in the above three cases not stated.

Kusmin: XXII and XXIII.—Cancer of esophagus. XXIV.—Cancer of stomach. XXV.—Recurrent cancer of breast. Duration and mode of treatment in these three cases not stated. No improvement. XXVI.—Serpiginous ulcer of forehead; cured.

Zarenin: XXVII and XXVIII.—Cancer of breast. XXIX and XXX.—Cancer of uterus. All four cases markedly improved; duration and mode of treatment not stated.

Vasilevski: XXXI to XXXVI.—Gynecological cases; nature of malady, duration and mode of treatment not stated; improved. XXXVII and XXXVIII.—Nature of cases, duration and mode of treatment not stated; not improved.

Fofius: XXXIX.—Cancer of labia majora; no improvement.

Kalabin: XL.—Cancer of uterus; duration and mode of treatment not stated; improvement.

Kelber: XLI.—Thirty-three years old; cancer of uterus, treated for six weeks; improvement. XLII.—Fifty years old; cancer of uterus, treated one month; no improvement. XLIII.—Twenty-seven years old; cancer of uterus, treated five weeks; no improvement. XLIV.—Cancer of uterus; marked improvement.

Denissenko: XLV to LI.—Cancer of breast; improvement. LII.—Cancer of uterus; improvement.

Robinson: LIII.—Fifty year old female; cancer of lower jaw; great improvement.

Poteyenko: LIV.—Forty-nine years old; cancer of uterus, treated sixteen days; no improvement.

Targowla: LV.—Forty-nine years old; cancer of uterus for three years; two months' treatment; great improvement. LVI.—Cancer of stomach; lady seventy years old; one month's treatment; great improvement.

Choladkowski: LVII.—Cancer of esophagus for nine months; could not pass smallest olive sound; internal treatment for two months; recovery as far as difficulty in swallowing and pain was concerned.

Dührsen: LVIII.—Cancer of uterus; no improvement.

Shirshov: LIX.—Cancer of uterus; treatment for six weeks; no improvement.

Spivak: LX.—Patient, male, fifty years old. Carcinoma of stomach; sick for ten months. Tumor occupied the whole anterior surface of stomach, extending below umbilicus. Greatly emaciated, no appetite, constant pain in abdomen, sleeplessness. Commenced treatment with ten drops of fluid extract of chelidonia.

which was soon increased to twenty-five drops three times daily. Stomach remained tolerant to the drug. The appetite markedly increased, the pains were allayed, and for hours patient would be free from them. This continued for eighteen days, when he became worse and died. LXI.—Male, forty-eight years old; carcinoma of the stomach, pyloric region. Patient sick for eight months. Cachexia, pain over site of tumor almost constant; appetite poor. Internal administration of chelidonium for three weeks. Showed signs of improvement. Appetite became better, color healthier, tumor did not increase in size and was somewhat softer to the touch.

#### SUMMARY OF CASES.

Out of the above sixty-one reported cases, thirty-three improved under chelidonium treatment, and twenty-seven showed no improvement, classified as follows:

Carcinoma of uterus (22 cases): Improved, 13; not improved, 9.

Carcinoma of esophagus (5 cases): Improved, 3; not improved, 2.

Carcinoma of breast (12 cases): Improved, 9; not improved, 3.

Carcinoma of stomach (6 cases): Improved, 4; not improved, 2.

There was one case of carcinoma of nose and one of carcinoma of glands of neck, both of which improved under treatment.

Two cases of carcinoma of lower jaw, of which one improved and in the other there was no improvement.

There was one case each of carcinoma of the eye, tongue, parotid gland, labia majora, ear, and back, in neither of which was there observed any improvement.

Two cases of epithelioma of lip; improvement observed in both.

One case of warty growths; no improvement.

One case of serpiginous ulcer; improved.

In two cases the nature of disease was unknown.

There were fourteen observers.

At the meetings of the various medical societies in Russia and Germany many discussions took place in reference to the action of the drug, and many cases were cited *pro* and *contra*, but as no detailed descriptions are given in the reports I did not include them in my paper.

The general sentiment, based upon the favorable cases reported by reputable physicians and the microscopic examinations of

cancerous tissue made after the injections, is (1) that the drug undoubtedly has some influence upon cancerous tissue which requires further investigation; (2) that the experiments are not numerous enough to warrant any definite conclusions; (3) that the drug being very unstable, many of the unfavorable cases may be attributed to the inefficiency of the preparation; and (4) that probably the technique of the administration is not yet perfected.

**A REPORT OF FOUR CASES SIMULATING  
STONE IN THE KIDNEY FOR WHICH  
NEPHROTOMY WAS PERFORMED;  
NO STONE FOUND; OPERA-  
TION FOLLOWED BY  
DISAPPEARANCE  
OF ALL SYMP-  
TOMS.\***

BY ORVILLE HOWITZ, M.D.,

Clinical Professor of Genito-urinary Diseases in the Jefferson  
Medical College of Philadelphia.

In four cases in whom I performed the operation of nephrotomy for a condition that simulated stone in the kidney, a most careful exploration of the kidney by palpation and puncture by means of the needle was made, and in two of the cases incision into the organ itself, yet no stone was found. These patients have all recovered their normal condition and health, and the anomalous symptoms for which the operation was performed have all disappeared.

The first individual was operated upon one and a half years ago; he was twenty-eight years of age, a blacksmith by occupation. He always enjoyed good health up to within eight months prior to his first visit to the Jefferson Hospital, when he began to suffer from a dull aching pain in the lumbar region, paroxysmal in character. At times the pain would extend along the course of the ureter into the testicles; it was increased by exertion and pressure. Palpation proved the kidney to be in its proper position, normal in size, but there was tenderness on pressure.

The patient stated that he never had any venereal disease, and on examining the urethra and bladder they were found to be healthy. The urine was normal in quantity; it was high-colored, and the alkaline tide, which should appear about three hours after partaking of a meal, was absent; it contained two per cent. of urea, and its specific gravity was 10.18, with uric acid in excess and albumen. Under the microscope epithelial cells and a few blood-corpuscles were detected. No pus could be found.

When the pain extended into the testicle the patient often suffered from frequent desire to micturate. The pain had become so constant that he was unable to pursue his occupation. He had been under the care of numerous physicians without relief. From the history of the case and the examination of the urine it was presumed that he was suffering from a stone in the right kidney, and an exploratory operation was performed. No stone was found. The patient left the institution on the fourteenth day after the operation, the pain having completely disappeared. He states that he has been in perfect health ever since.

The second case was brought to me by Dr. Harris, of Wilmington, and was operated upon before the class in May last. At that time he gave the following history: He was forty-five years of age, a laborer by occupation; had enjoyed perfect health up to two years previous to his admission to the hospital, at which time he began to suffer from pain in the small of the back, on the left side, which would at times extend to the testicle. At first the pain was paroxysmal in character; it would be severe for several hours, then gradually subside and finally disappear; it would remain absent for two or three weeks, only to return with renewed force. As time went on the attacks became more frequent; the intervals between the remissions gradually shortened, until at the time of his admission it was almost constantly present. Sometimes the severe attacks of pain were associated with slight nausea. His urine at times was thick, especially after a severe paroxysmal pain. Had never passed a calculus, nor blood. Lately he had been losing in strength, and the pain prevented him following his occupation. Hitherto the numerous remedies prescribed failed to bring relief.

There was no venereal history. On examination the urethra, prostate and bladder were found to be normal; the left kidney was in its proper position, but sensitive to the touch.

\* Read before the Surgical Section of the College of Physicians of Philadelphia.

The specific gravity of the urine<sup>was</sup> 10.20; it contained two per cent. of urea and the phosphates were present in excess. The microscope showed the presence of epithelial cells, blood-corpuscles, but no pus.

The method of operation in this case was that recommended by Edebohls. The kidney was easily delivered, but great was the disappointment when no stone could be discovered, either by ocular inspection, manipulation, or multiple puncture with the needle. I was so confident that a stone was present that I was unwilling to restore the kidney to its normal position without a most thorough examination, knowing that a calculus of small size might easily escape the most careful search, unless indeed the kidney was opened. Accordingly an incision was made along the posterior border of the organ, large enough to admit of the entrance of the index finger and allow me to examine the calyces. No stone could be found. During the incision into the substance of the kidney an assistant grasped the pelvis, with the blood-vessels between his index finger and thumb, thus preventing the usual free bleeding which follows this procedure.

The wound in the kidney was packed with iodoform gauze, a drainage tube inserted, and the skin and muscles closed by means of interrupted silkworm-gut sutures. The patient made a quick and rapid recovery, and has had no reappearance of his troublesome symptoms since the operation. He is to-day in perfect health.

The third patient, whom I operated upon two years ago, was afflicted with a fistulous opening in the left lumbar region, which led to the kidney, through which all the urine eliminated by the organ on that side was discharged. The skin of the back was excoriated, consequent upon being constantly bathed in urine. He was much below par and was gradually losing health and strength.

Five years before coming under my care he was operated upon by the late Professor Agnew for a large perinephritic abscess with stone in the left kidney. To empty the abscess properly it became necessary to keep the drainage tube *in situ* for a long period, and its removal was followed by a fistulous opening which refused to heal. Every surgeon by whom he was seen since the operation advised nephrectomy. I suggested an exploratory operation in order to examine the local condition, and to save the kidney if possible. The patient consented; and the kidney was exposed in the usual manner. In

the body of the organ a fistulous opening was discovered large enough to admit the index finger, and a long tract was found extending down into the pelvis, being apparently the remains of the perinephritic abscess. The tract was scraped by a curette and the cicatricial tissue surrounding the sinus in the kidney was cut away by means of a small bistoury. The wound was packed with iodoform gauze and dressed in the usual manner. To my surprise it began gradually to granulate and closed entirely in about three months. It has remained so ever since.

For two years the patient had been suffering with all the symptoms of stone in the right kidney. As it is not very unusual for renal calculi to be found in both kidneys a second operation was advised, but such was the individual's dread of having a similar experience with his right to that which he had undergone with his left side that he refused all surgical interference. Medical treatment had been fairly tried, but brought no relief.

When his left side healed up his confidence was restored, and he permitted me to make an exploratory nephrotomy on the right kidney; the organ was exposed by the Edebohls method, and the kidney structure incised so that a digital examination could be thoroughly made, but no stone was found. On convalescing, the pain from which the patient had suffered had completely disappeared, and within a year he had gained forty-five pounds and enjoyed good health.

The last of this interesting group of cases was that of a young man kindly sent to me by Dr. Hirst, of Camden, upon whom I operated four months ago, no stone being found. His history is briefly as follows: He had never had any venereal disease, and was in perfect health up to two years before, when he began to suffer from attacks of pain in the right lumbar region. The pain would at times descend into the right groin and testicle; finally he suffered from a constant pain in the back, especially on the right side, which was increased on exertion. When the pain descended to the testicle that organ became markedly retracted, and there was attendant slight nausea. The urethra, bladder and prostate were in a normal condition; the urine contained epithelial cells, with a slight number of blood-corpuscles, and albumen. Since the operation he has gained in weight and his pain has completely disappeared.

The questions naturally asked when discussing these four cases, where every symp-

tom of stone existed except the voiding of renal calculi, and where no stone was found on exploring the kidney, are: What are the reasons for the patient's suffering? And why after recovery from the operation was there permanent and entire cessation of all the symptoms for which the operation was undertaken?

The only way in which I can answer these queries is to offer an explanation which has already been suggested. It has been surmised that probably the kidney on the side affected is somewhat more movable than it should be, yet to so slight an extent as to be impossible of detection by manipulation. By some means or other the kidney becomes slightly misplaced and thus temporarily the ureter becomes bent upon itself, blocking up and preventing the flow of urine; thus there is a distention of the pelvis of the kidney which probably gives rise to the pain. The frequent distention of the pelvis with urine owing to the blocking of the ureter might in time light up a slight pyelitis, which would likewise account for the presence of epithelial, blood- and pus-corpuscles in the urine. The operative procedure necessary to examine the kidney is followed by more or less adhesive inflammation and the formation of cicatricial tissue around the kidney, which tends to hold it in place and thus prevent any further kinking of the ureter.

Many operators have had an experience similar to mine, hence it should not be a subject of annoyance if the surgeon have a patient who presents all the symptoms of calculus in the kidney and when the operation of nephrotomy is performed no stone is found, for experience seems to show that even if the stone is absent the symptoms calling for the operation will all disappear, and the patient will be restored to health.

The method of operation first described by Edebohls is recommended, not only because it permits of a better ocular and manual examination of the kidney, but if it should be necessary to incise the organ it can be done without loss of any appreciable quantity of blood.

In conclusion I offer this suggestion: Never be satisfied that a stone is not present until you have had a chance to make an ocular inspection of the kidney. Very recently I assisted an operator in a case of this kind which has made a deep impression upon me. The patient had every symptom of stone in the kidney; nephrotomy was performed by means of the old oblique incision; multiple punc-

tures by a needle, were made; but no stone could be detected. The patient recovered from the operation and returned home. Six months later he again came under the surgeon's care, suffering from the same symptoms, but greatly intensified. The operator decided to expose the kidney once more, and endeavor to discover the cause of pain; failing to do this he had determined to remove the organ. The old wound was reopened, manipulation and puncture by means of a needle were again resorted to, but no calculus could be detected. The wound was enlarged and the kidney separated from the adhesions and made ready for ligation of the pedicle, preparatory to removal. On bringing the organ out of the wound and turning it over a small stone was found at the under and lower border of the kidney in its substance. This was removed, and the patient made an excellent recovery.

In a paper recently read before the Medical Society of London, by Mr. Reginald Harrison, he reports three cases of his own and two of Newman's, of Glasgow, whose symptoms were somewhat similar to those recounted in the preceding cases. In the first case the patient had suffered from an attack of scarlet fever three weeks previously. The symptoms were those of intense pain in the loin, the urine containing albumen and pus. Nephrotomy was performed and the kidney structure incised, and nothing found, the albumen gradually and completely disappearing. The second case was one of nephritis from exposure to cold and damp; there was great pain in the right lumbar region; urine loaded with albumen. An operation was followed by the disappearance of all morbid symptoms. In the third case the patient had passed a small calculus, and there was great pain in the region of the left kidney which, on palpation, was found to be swollen and tense. It was opened and explored; no stone could be discovered. The patient made a complete recovery and the albumen completely disappeared. Newman's two cases were those of movable kidneys with a kinking of the ureter, leading to hydronephrosis; there were albuminuria and tube-casts in the urine—all of which completely disappeared after nephrotomy.

The cases reported by Newman are similar to those recited by myself, whilst those that came under Mr. Harrison's care were a form of albuminuria due to kidney tension, and were relieved by renipuncture. In his paper on the subject Mr. Harrison calls attention

to the fact that where albuminuria is due to renal tension, though both kidneys be similarly involved, it is unnecessary to operate upon both organs as the sympathy which exists between the two glands is such as to cause an impression upon one to be reflected upon the other. Relief afforded to one kidney, as his cases would seem to illustrate, usually assists the other; whilst, as is well known, when the secretion on one side is suspended or arrested the opposite organ speedily takes up the whole of the work.

---

*THE ADVANTAGES OF RESIDENCE BY  
THE SEASIDE.*

---

BY WM. EDGAR DARNALL, M.D.,  
Atlantic City, N. J.

---

Atlantic City has justly earned a world-wide reputation as a winter and summer health resort. Its autumn climate entitles it to perhaps as much if not more consideration as a resort for invalids during the fall months. The sanitation of this populous resort is always in a good condition, because under the careful supervision of an excellent Board of Health it is kept up to the standard throughout the year. The city is always clean, and strict vigilance is maintained day in and day out by the authorities. Such even pace is kept with the large crowds who frequent the place, that the day after they leave the city is as clean as it was before they came. The streets are constantly scraped, and all refuse is collected and carried off by garbage-carts as fast as it accumulates. Swill-barrels are emptied with regularity, daily trips are made the year through to the garbage depot, and everything collected by this systematic process is consumed by fire. The sewerage also represents the best system known to hygiene.

Every effort has been expended by the authorities to furnish the city an adequate and at the same time pure water-supply; they have succeeded admirably in this. Bad water is the bane of many resorts, but Atlantic City can boast of as pure water as may be found anywhere; this is obtained from springs and artesian wells. These latter are sunk from 750 feet to 1400 feet below the surface.

Geologically the island on which this city by the sea is built is composed of a superficial layer of sand some six hundred feet in thickness; underlying this is a stratum of clay,

which in turn lies upon a marl layer. This marl is peculiar in its formation, being composed almost entirely of a shell concrete. This stratum crops out in many places along the Atlantic coast, and is the same that forms the well known marl beds of North Carolina and Virginia. Underneath this shell-layer lies a bed of gravel; it is from this latter that the artesian supply is furnished, and these streams of pure and limpid water are beyond even a suspicion of pollution.

There are many things that go to make the autumn in most localities peculiarly a breeder of certain infectious diseases, such as diphtheria, malaria, typhoid and other fevers. In a large number of these cases the infection may be traced directly to the drinking water.

Nature has selected this season of the year to put off her garment of green and prepare herself for the ermine cloak of winter. Decaying vegetation is therefore abundant and provides an excellent medium for the growth and development of certain deleterious organisms. The heavy rains of this period, drenching the soil, easily bear these organisms to the water-supply unless great care is exercised. In addition to this, cooler nights with warm days effect a greater atmospheric precipitation, and the percentage of dew formation is increased. Bacteriological investigation teaches us that just this kind of fluctuation between the damp and the dry, with a sufficient degree of heat—and this is provided by the balmy days of this period—furnish the most propitious condition for the propagation of germ life. Thus we have in the autumn almost ideal surroundings for the growth of bacteria, and often an easy channel by means of surface drainage through which the water-supply becomes polluted.

The question may well be asked, then, Why is it that this city of 23,000 inhabitants, often accommodating 150,000 to 175,000 summer visitors at a time, is so free from infectious diseases of all kinds, and when sporadic cases do occur the infectious process is so easily stamped out, while in other places ruthless epidemics mow down their victims? This question is not difficult to answer when the facts are known. Two factors are especially important: (a) an abundance of sea air highly charged with ozone; (b) a porous, sandy soil, with scant vegetation.

As referred to above, the bacteria require for their propagation warmth, moisture, and a suitable pabulum. The decay of vegetable matter furnishes this pabulum; but as very little vegetation grows upon the sandy soil

of Atlantic City there is little decay, and the germ starves for want of the food necessary to its existence.

Again, whatever moisture the ground receives soon percolates through the sand, leaving the already enfeebled bacterium—struggling for existence and in want of water—high and dry and thirsty. An ocean breeze, highly ozonized, perhaps now sweeps down upon its defenseless condition. Oxygen and germ life are deadly enemies. The latter is too much weakened to resist; it quickly succumbs, and its innocuous life-history is ended. It is clear therefore that such climatic conditions as these do not present the most salubrious surroundings for the proliferation of these deleterious organisms.

Nature has supplied Atlantic City with her most potent antiseptic—plenty of pure ocean air; while the wisdom and artifice of man have given her the rest—pure water, excellent sewerage, and careful sanitation. This condition of natural antiseptis under which the people live, along with what hygiene has accomplished, makes the very climate to a great extent prophylactic against infectious diseases. Of course such diseases now and then crop out. Sporadic cases may occur anywhere; no place is entirely free from them. It frequently happens in these cases that the patient has been infected before leaving home, but the disease does not develop itself until he has been here for a few days. Epidemics, however, are entirely unheard of.

The practical immunity of this climate from malaria makes its autumnal period especially advantageous to that class of chronic cases whose susceptibility to paludism causes them to dread the periodical attack of malaria they are accustomed to have at this season. A short stay here frequently allows them to escape the attack altogether.

Much relief is also experienced by sufferers from autumnal catarrh, or hay fever. It is probable that the small amount of flowering vegetation, along with plenty of good wholesome air, are important factors in affording them relief from this distressing disease.

Nor can better tonic treatment be recommended to neurasthenics, anemics, and convalescents from surgical operations or exhausting zymotic diseases than a short stay at the seaside. The bracing air makes exercise a pleasure to the enfeebled and gives them energy; deeper breathing is encouraged; the appetite improves; the system is thoroughly invigorated. Roses soon tint the

blanched cheek of the invalid; new life infuses every vein; and the consciousness of returning strength inspires new hope and courage to the depressed.

In autumn the natural beauty of the scenery is enhanced. Autumn brings in its train beautiful balmy days with glorious sunsets. The sun sends down its rays in long, slanting pencils of light to the water, and the water spreads itself out in variegated, ever-changing tints of green, purple, pink, and amber. The temperature is delightful—neither too cool nor too warm. The dreamy period of Indian summer prolongs these delights far into winter, until it has robbed it of half its rigor.

The accommodations of elegantly equipped hotels surround hotel life with all that is desired by invalidism in the way of personal comfort. Perfect quiet and freedom from excitement may be obtained as easily as at home, for the tide of the summer's rush has ebbed, and the restless, eager sea of human faces has given place to quiet and calm.

Congenial surroundings and pleasant things for the mind to dwell upon are indispensable to the rapid upbuilding of the invalid. For this reason every practitioner recognizes the value of an occasional "change" of scenes and faces for his patient. It is a diversion for the mind. Just those moral surroundings so needful to the recuperation of convalescents are furnished by this climate.

After the rush of August a genial air of relaxation pervades everything. The pleasant temperature is grateful to the sick one. The water presents its fairest charms, bathing is good till October, and the peaceful, restful scenery affords food for healthy meditation. Returning strength begets new courage; returning health inspires new interest in life; and the patient, who perhaps has been brought low by disease, is restored to his friends a well man.

*THE TECHNIQUE OF PROFESSOR KEEN'S  
SURGICAL CLINIC IN THE JEFFERSON  
MEDICAL COLLEGE HOSPITAL.*

---

BY THOS. LEIDY RHODES, M.D.,

Assistant Demonstrator of Pathology; Assistant in the Surgical Clinic, Jefferson Medical College Hospital.

---

[Continued from page 164.]

On arriving at the hospital the surgeon and assistants remove their coats and waistcoats in the surgeon's private room, roll up

their sleeves above the elbows, and put on freshly laundered white linen coats with short sleeves. The surgeon enters the clinic and scrubs his hands and forearms with pyoktanin-etheral soap, or with green soap, and a brush for at least five minutes. This primary cleansing is done before the students at each clinic as an object lesson to them. Having dried the hands, the nails, which are always kept reasonably short and evenly trimmed, are thoroughly cleansed with the ivory instrument made for this purpose, or with the blunt-pointed orangewood sticks with which the clinic is supplied. The hands and forearms are bathed in alcohol and finally scrubbed with a sterile brush in the bichloride of mercury solution 1:1000. The surgeon puts on a long rubber apron, and over this he wears the linen operating gown, the loose sleeves of which are drawn above the elbows and tied snugly with tapes.

The assistants, who have previously disinfected their hands in a similar way, in the meantime see to the immediate preparations for operation.

The assistant who will have charge of the instruments refers to a Keen "Instrument Blank," and selects from the instruments in the racks those necessary for the operation to be performed. These are wrapped in pieces of gauze to facilitate their handling and put into the Schimmelbusch sterilizer, where they are boiled thirty minutes, one per cent. of soda being added to the water to prevent their rusting. Paired instruments are separated before boiling; cutting instruments are separately enveloped in cotton to retain their sharp edge; needles are wrapped in a separate piece of gauze. Two all-metal hypodermic syringes are boiled at the same time, for the anesthetist's use. If the operation be on an extremity, the Esmarch apparatus is immersed in a five-per-cent. carbolic solution and remains in this solution until needed. The sterilized trays are placed in position on the glass tables for holding the instruments after they are boiled, and hot sterilized water is poured in the trays, which are covered over with towels.

The assistant in charge of the ligatures and sutures immerses the jars containing these in mercuric chloride solution 1:1000, removes the tops, and lifts from each with a sterilized tenaculum the necessary quantity of catgut (wound in rings) and drops it into sterilized bowls containing absolute alcohol. The ligatures are cut into twelve-inch lengths, the quantity being estimated for the kind of

operation to be performed. Spools of silk are likewise emptied from their separate tubes into sterilized bowls containing absolute alcohol; silkworm-gut and kangaroo tendon remain in their respective jars until needed.

The clinic nurse and her assistant, having disinfected their hands, cover the tables with sterilized sheets and arrange the jars on them properly and make up the different solutions.

At the beginning of the clinic the patients from the last clinic are brought in from the wards, on rolling beds, and brief remarks made upon the progress of each case; the wounds are dressed before the students so that they can note and keep in touch with the proper methods of dressing cases. The result of the pathologist's examination in the case is also read to the class, and while this is transpiring the chief clinical assistant inspects the preparations and sees that everything is in perfect readiness for operation.

The *anesthetic* is administered in a room apart from the clinic in order that the disturbance to the patient's nervous equilibrium, which would be brought about by bringing him while still conscious before a large body of students, may be avoided, and that he be spared the sight of the immediate preparations for operation and the necessary display of instruments. Occasionally the anesthetic is administered before the class for the purpose of instruction. The administration of the ether (which is commonly used for anesthesia) is not commenced until all the preparations in the clinic are nearly completed and the surgeon is ready to proceed with the operation; the practice of anesthetizing the patient before preparations for the operation are completed, and sustaining the anesthesia until the surgeon is ready to proceed, is discountenanced.

In order that the intervention of the operator will not be necessary during the process of anesthesia, should the patient show signs of failing heart or respiration, a skilled and trustworthy assistant is selected to give the anesthetic, who is competent to act in case of emergency. The anesthetist's whole attention is devoted to the administration of the drug, and he is not allowed to watch the operation.

For administering ether the form of inhaler devised by Dr. Allis is used on account of its simplicity, lightness, and efficiency. For chloroform the Esmarch inhaler is used, except as described below. The anesthetist uses a bottle graduated in centimeters and

having a Tweed dropper. Squibb's ether and chloroform are invariably used. The anesthetist is also supplied with mouth-gag and tongue forceps. An assistant has charge of the hypodermic syringe, which has been tested beforehand to see that it is in working order, and brandy and solutions of strychnine, atropine and digitalis are placed on a small table within reach.

Before exhibiting the anesthetic the anesthetist examines carefully the heart and lungs, loosens any constriction around the neck, chest or waist, and inspects the mouth to see that it contains no false teeth or other foreign body, as tobacco. The patient's statement is not accepted in this matter, but personal inspection is necessary, for it is quite common for patients to deny the presence of false teeth.

While heart disease is not considered a positive contraindication to the administration of an anesthetic, its presence makes the anesthetist more wary, and in valvular lesion the administration will be made with especial care. The heart-beat usually improves under the judicious administration of ether. It is true that anesthetics are highly dangerous in people with fatty hearts, but the shock of operation without anesthesia is equally or even more dangerous, and the surgeon has the choice of the lesser of two evils. The presence of extensive capillary bronchitis also offers a more or less serious drawback to administering the anesthetic, as the amount of mucus secreted may cause asphyxia, and the least amount of the anesthetic is given that is capable of producing the desired effect. In these cases chloroform is generally used by preference, and if care is taken in the administration there is seldom any serious result.

The urinary report is examined beforehand to ascertain the condition of the kidneys; the presence of albumen and casts in the urine, while not contraindicating operation, make the peril of anesthesia greater, and certain dangers are to be watched for and guarded against. But while in these pathological conditions of heart, lungs and kidneys there is more danger than where these complications do not exist, there is really no condition of these organs, as Hearn has clearly proved, that offers a positive contraindication to the use of an anesthetic in a case requiring surgical interference.

Inquiry is made as to the patient's habits, whether he be addicted to the use of alcohol or not. Alcoholic patients are peculiarly

liable to congestions, and pass through the exciting stage of anesthesia with considerable struggling. These cases are usually given a hypodermic injection of morphine a short time before leaving the ward to aid in bringing about insensibility with very little of the anesthetic.

Ether is the drug commonly used for anesthetizing in the clinic, as it is less dangerous in general cases, though it is not as agreeable to take and slower in action than chloroform. However, the sudden and alarming syncope which chloroform induces occasionally may come on so rapidly that it may prove fatal almost before an attempt can be made to revive the patient, and it is for this reason that it is not more generally employed. As Hare has shown by experiment, chloroform may kill by paralysis of the vasomotor and respiratory centres as well as of the heart, whereas ether acts fatally through the respiration alone, the heart rarely being affected. In case of alarming symptoms from ether there is usually sufficient time to undertake means of resuscitation which are likely to be of avail. Practically the only cases in which chloroform is selected are those in which there is profuse bronchial secretion or advanced kidney disease, and in operations on the mouth and nose, where it is administered on a pledget of cotton held in a forceps so as to interfere as little as possible with the movements of the operator.

Having ascertained the condition of his patient the anesthetist assures him there is no danger, and the patient being recumbent the dry inhaler is placed over his face, letting him take several respirations to gain confidence. He is instructed to take deep inspirations and not to expel the air too rapidly. This method of breathing allays to a certain extent the supersensitiveness of the bronchial mucous membrane, and the ether is received more kindly and is not apt to produce coughing. Only a few drops of ether are poured in the inhaler at first; this is repeated every few minutes, the anesthetist giving the patient time to become accustomed to the vapor and to acquire confidence, and encouraging him to take it quietly and not to be alarmed. A little patience exercised at the outset proves a saving of time and trouble in securing the desired effects, and the result is a much more satisfactory anesthesia, with less shock than where the ether is crowded and force is used to restrain the struggles of the patient.

As soon as the patient is fully under the

influence of the anesthetic he is wheeled on the rolling table, on which he was etherized, to the operating arena, where he is lifted to the operating table.

While the operation is in progress certain *complications* of the anesthetic state are liable to arise which must be met and treated the moment they occur. Of these, vomiting is the most common, and while it is disagreeable to the operator, particularly if he be operating about the face or performing a celiotomy—the vomitus being liable to infect the wound in the former case, and the rigid muscles from straining interfering in the latter—the danger lies in the fact that a part of the vomitus may pass the glottis and enter the trachea. The local anesthesia of the parts interferes with the usual guarding of the passageway to the lungs, and the patient may become asphyxiated from particles of food lodging in the trachea or bronchi. The necessary precaution is taken to guard against this occurrence by withholding food for at least five hours before operation. The anesthetist knows that his patient's stomach is empty, so has nothing to fear from this source, for should some of the vomited matter enter the patient's trachea, being nothing but a thin frothy mucus, it can do no damage to the mucous surface; the principal harm is that it interferes with the progress of the operation and causes much cardiac depression if long continued. Vomiting is usually due to incomplete anesthesia, the admixture of too much air with the vapor. The patient's head is lowered and extended and turned to one side, so the material may be drained off in a towel and the anesthetic persistently administered until vomiting ceases and complete relaxation occurs.

Bronchorrhea may be a distressing complication to the administration of the anesthetic, inasmuch as the free secretion in the bronchi and bronchioles may interfere with thoroughly anesthetizing the patient, and the patient is more prone to nausea from swallowing much of the mucus which is heavily soaked with ether. Bronchorrhea usually occurs during the earlier stages of anesthesia, and if judicious care is taken not to force the ether from the start the mucus secreted will usually not be of an amount sufficient to cause any distressing symptoms. When it occurs the patient's head is turned to the side and the mouth wiped frequently with a small gauze sponge in a sponge-holder to get rid of the accumulation.

Cyanosis in greater or less degree may

occur in the early stages of anesthesia, just before the stage of relaxation or later in the progress of the anesthetic. In the former case it usually occurs where bronchorrhea is profuse, and if the cyanosis be only slight the ether is continued until the patient is relaxed, and the bronchial secretion is drained off as rapidly as possible by wiping out the mouth frequently with a gauze sponge. If the cyanosis becomes marked, however, and the trained eye of the anesthetist recognizes an alarming condition, the ether is suspended and efforts made to revive the patient. During the progress of the anesthesia cyanosis may come on from closure of the epiglottis or "swallowing the tongue." When the condition becomes alarming the inhaler is removed, the patient's head is brought over the edge of the table and forcibly pressed backwards. This maneuver lifts the hyoid bone and with it the epiglottis. Cold water is at the same time dashed on the face with a towel. Should this not suffice the mouth-gag is fixed in position and the tongue pulled forward, rhythmical traction being made by means of a forceps with a prong on one blade which transfixes the tongue; this does far less injury to the tongue than forceps which act only by pressure. The throat is cleansed of mucus and the epiglottis lifted by pressing forward the base of the tongue with a blunt instrument or the finger. Artificial respiration by Sylvester's method is rarely necessary. Hypodermics of strychnine, atropine, digitalis or brandy may be necessary for a failing pulse or shallow respiration.

When it is deemed more advisable to use chloroform for anesthesia the Esmarch inhaler is generally used, but where operations on the mouth demand all available space and light after the patient is fully anesthetized, it is administered on a pledget of cotton clamped in a forceps. The cotton is held several inches above the mouth so that the chloroform vapor will be well mixed with air. The lips and nose are smeared with cosmoline to prevent blistering, and the utmost precaution is taken to anticipate syncope. Should this occur, means to counteract it are instantly taken. The chloroform is suspended, the head is lowered and thrown back, and the tongue drawn rhythmically forward, and if this does not suffice artificial respiration is practiced at once without waiting for the breathing to cease. An assistant gives a hypodermic injection of ammonia, followed by  $\frac{1}{16}$  of a grain of strychnine sulphate. The artificial respiration is kept

up for some time to urge the blood through the heart, and hypodermics of brandy and strychnine repeated at short intervals until improvement occurs. The writer has given thirteen hypodermic injections of strychnine of  $\frac{1}{10}$  of a grain each within two hours in such a case before the heart finally regained its accustomed beat. There were no ill after-effects from the cumulative action of the drug.

If necessary, faradism is used over the phrenic nerve (one pole over the epigastrium, the other over the course of the phrenic at the root of the neck) and mustard applied over the heart and cervical spine. Such procedures are rarely called for, however, if the drug be administered very slowly and plenty of air be mixed with the vapor. The writer has seen but two instances in which active measures were demanded to resuscitate the patient while chloroform was being administered, during a period of seven years in the Jefferson Clinic. Both of these recovered, the operation being temporarily suspended in each case. In one of the cases it was necessary to completely invert the patient, holding him up by the legs and compressing the abdomen rhythmically (which Hill has shown to be the best means of resuscitation) until the circulation was re-established and he showed signs of returning respiration. Such extreme procedures are fortunately, however, rarely demanded.

*The Operation.*—In the selection of a typical case for description of operative technique as practiced in the clinic we have a wide choice. The region of the neck, with the variety of tumors and cysts that are liable to be found here, is probably invaded as often as any other part of the body. Most of these growths are of glandular origin, and many of them are malignant, so the case before us, we will then suppose, is a lympho-sarcoma of the neck which has not yet assumed such proportions or invaded the tissues so extensively as to make operative measures unjustifiable.

The fully anesthetized patient, having been lifted to the operating table, is covered with warm woolen blankets, the edges being tucked under his back to reduce as far as possible the loss of body heat, and if necessary he is surrounded by hot-water bottles to supply by artificial means enough heat to make up the deficiency of the amount that may be lost. This will greatly lessen the subsequent shock which often follows a prolonged dissection. The temperature of the room is kept at a reasonably comfortable

mark, and drafts are avoided. To prevent his becoming chilled from the solutions these are always used quite warm and the table is placed in a slight Trendelenburg position, the foot being raised about three or four inches above the level of the head, so that all fluids run towards the head. This avoids wetting the blankets and other clothing and is insisted upon by Professor Keen in all operations on the head, neck and breast as a minor but important point in the technique.

The dressings are then removed and the face, neck, chest and arms to the elbows are scrubbed with soap and water, rinsed off with water and dried, and washed with alcohol. For this scrubbing a special brush reserved for the patient is used. A sterilized sheet is thrown over him, with the ends hanging over the sides and foot of the table, and fastened over his shoulders. The head is encircled with a sterilized towel, covering all the hair, and a sand pillow wrapped in a sterilized towel is placed under the shoulders to raise them and allow the head to drop backward. A sterilized towel is wrapped around the inhaler. The operative area is finally scrubbed with solution of bichloride of mercury 1:1000, care being taken that none enters the eyes or nasal and buccal cavities; and after plugging the external ears with sterilized cotton the part is ready for operation.

Notwithstanding these painstaking efforts at repeated cleansings, the staphylococci *epidermidis albi* are still found in the deeper layers of the cuticle, their accustomed habitat, but as they rarely show any tendency to pathogenesis and have never more than a local significance the rôle they play in the future proceedings is usually only one of slight importance.

The two immediate assistants, both of whom wear sterilized operating gowns so as to have perfect aseptic relations with the surroundings, take their proper positions at the table, the chief assistant to the operator's right, the second assistant opposite him. The assistant in charge of the instruments having removed them from the sterilizer and laid them in trays containing sterile water, selects a sharp scalpel and dissecting forceps, which he hands to the operator, and clamps a dozen or more hemostatic forceps to the sterilized sheet covering the patient, where they can easily be reached by the assistants. Fastening the forceps in this way to the sheet prevents their falling on the floor. A basin full of dry gauze sponges stands on a table within easy reach. The fourth assistant busies him-

self with the ligatures and sutures, cutting them into proper lengths, and threads the needles. Two nurses with aseptic hands look after the solutions, which they change frequently, and hand sponges, dressings, etc., when needed.

The patient's head is turned to one side and held firmly by the anesthetist, sterile gauze pads are pushed back of the neck on each side to absorb blood, and the operation is begun by making a free incision over the growth in the line of the sterno-cleido mastoid. After the platysma and fascia are divided the deep fascia is opened the whole length of the incision. The veins that are encountered in these superficial dissections are clamped and divided. The sterno-cleido will usually be found adherent to the growth and stretched over it. From now on the dissection will often be most difficult and tedious, and demands the exercise of the highest qualities of a capable surgeon. There is probably no other procedure in the category of surgical operations that is more difficult to perform, more serious in its demands, dealing with so infinite a variety of perverted relations. The growth is apt to be fixed on all sides by adhesions which are not readily separated, and the topography of the part is wholly altered.

When the anterior surface of the growth is reached, the next step is to attack at once the most dangerous region—the inner margin—where are found the vessels in the carotid sheath. This is accomplished principally with the Allis blunt dissector, which has justly been denominated one of the most useful of all surgical instruments. Two or three sharp curved retractors are used to great advantage to separate the tissues from the tumor, their location being changed frequently as the dissection continues, and the tumor also is pulled and rolled out by them, rather than seized by vulsellas, in the most advantageous way to aid in its extirpation. No tissue is cut or torn by the dissector until it has been carefully examined. One assistant sponges continually and is ready to make digital pressure should large vessels be wounded, while the other clamps the bleeding vessels as soon as they are cut. Hemorrhage is often serious owing to the numerous vessels which are large and thin-walled, especially if the tumor be of rapid growth. If these vessels are small and cannot be isolated from the tumor they are temporarily clamped and incised, but if they are of any material size a double ligature is at once thrown around them and the vessel cut be-

tween the two. The jugular itself may be so connected with the malignant growth that it will be impossible to isolate it, and it is accordingly divided between two ligatures, and no serious results follow the division. If it be wounded slightly a lateral ligature of fine silk mends the rent. The writer has seen the internal jugular unavoidably torn or cut on several occasions, and each time air entered the vein—in one of the cases air being sucked in five times—without the slightest untoward symptom. If this accident occurs the rent is instantly closed by the finger till the vein can be tied.

The growth may extend deep down into the tissues of the neck, and may have so insinuated itself among the various structures as to make this part of the operation most difficult and even desperate. The recurrent laryngeal presents a source of danger and, together with the phrenic, pneumogastric, sympathetic, and descendens noni, is to be avoided.

The dome of the pleura may be injured, and air be sucked into the pleural cavity. Should this occur the opening is at once clamped with forceps and closed with a running catgut suture, or is packed with iodoform gauze. A small amount of air in the pleural cavity will not be of any serious consequence and will soon be absorbed.

The posterior surface of the tumor is dissected loose and the mass rolled over by means of the sharp retractor, and the dissection continued until it is finally removed. Attention is now paid to the bleeding vessels. The smaller vessels are controlled by torsion, the larger ones ligated with strong catgut or fine silk, oozing from the tissues being controlled with successive gauze pads wrung out in hot water, and applied to the raw surface. Should bleeding points persist after the application of hot water they are controlled by additional catgut ligatures. Clots are removed by flushing with hot sterilized water or salt solution, and the wound dried with a gauze pad. Bichloride of mercury solution is not applied to the wound as it is irritating to the tissues, and when used upon albuminoids like blood forms chemical combinations which are not antiseptic, and which may account for untoward effects of disinfection in former years.

If drainage is required a fenestrated rubber drain is sewed in the lower angle of the wound, and the incision closed with interrupted silkworm-gut sutures passed with a curved needle, the suture at the upper end of

the wound being tied first; and as each successive one is tied an assistant makes pressure over the incision with a sponge to obliterate the wound cavity. No iodoform or other dusting powder is used. The anesthetic is stopped. An abundant gauze dressing is applied around the neck, over this a thick pad of sterile wood wool, and occasionally a piece of rubber dam on the outer surface of sufficient size to overlap the edges of the dressings. This is held in place with a wet gauze bandage, and a dry cotton bandage is applied over all, passing under the axilla, across the chest, around the head and over the back to hold not only the dressings but also the head in rather firm position. In place of wood wool the much cheaper pads made of the finest "excelsior" (the stringy wood shavings used for packing fragile articles) are sometimes used. The excelsior is made into pads of various sizes by means of gauze and then sterilized.

The patient is lifted back to the rolling table, warm blankets are wrapped around him, and the anesthetist accompanies him to the ward where his bed has been thoroughly warmed with hot-water bottles. He is placed in bed and hot-water bottles are disposed around him, care being taken that he will not be burned, and he is carefully watched until he is fully out of the anesthetic and intelligence is entirely restored.

In all operations the general technique is practically the same, additional features being used as demanded by each separate case. In operations about the nose and mouth, in many of which a preliminary tracheotomy is usually recommended, Professor Keen nearly always avoids this additional operation by placing the patient in the full Trendelenburg position, that is to say at an angle of thirty-five to forty degrees. Blood, like water, cannot run up-hill, and this position avoids the difficulties which often arise from blood half-choking the patient and also the later great danger of aspiration pneumonia. By turning the head to one side most of the blood runs out of the mouth and the rest is easily removed by gauze sponges in forceps. This posture is used in all cases of cleft palate, tumors of the tonsil, nose, or pharynx, removal of the tongue, cancer of the lip, hare-lip, removal of the upper or lower jaw, etc. When a celiotomy is performed for the extirpation of abdominal tumors and operations on the viscera, the moment the abdomen is opened the chemical antiseptic solutions are replaced by sterile salt solution.

To retain the intestines and keep them from encroaching upon the site of operation, Ashton's pads play a useful part. The required number of pads are kept in sterile water after they have been boiled, and a nurse has sole charge of these during operation. She prepares her hands and forearms by scrubbing with soap and water, rinsing with water and alcohol, and disinfects by the method employed by Kelly; the hands and forearms are immersed above the elbows in a saturated solution of potassium permanganate at a temperature of 110° F. until the skin is colored dusky-brown. This color is removed by a second immersion in a saturated solution of oxalic acid, at the same temperature, and rinsed in warm, sterile salt solution. She wrings out the pads in one pan of sterile water and transfers them to another until needed. The water in these pans is changed frequently by the nurse who attends to the solutions, the nurse having charge of the pads handling absolutely nothing but them alone. The number of pads used is not trusted to the memory but is written down on a blackboard, so there will be no controversy at the end of the operation whether any pads are missing, the number at hand corresponding to the number on the board.

Sterilized sheets cover the patient with the exception of the area disinfected for the operation, and towels are used sparingly as they have a tendency to become misplaced, especially if the patient struggles, not being fully under the influence of the anesthetic. As soon as the patient leaves the clinic the soiled sponges and dressings are removed, the floor is mopped with bichloride solution, the operating table is cleansed, and the soiled sheets on the tables are replaced by clean ones. Instruments and needles are gathered from the trays and scrubbed with soap under the hot-water tap; they are wrapped in gauze, the blades of the knives being enveloped in cotton, and resterilized by boiling while the next case is being anesthetized, additional instruments being added according to the requirements of the case. Fresh solutions are made up and the surgeon and assistants disinfect their hands and don clean operating gowns. In order to avoid the possibility of carrying infection to other cases, even with this careful technique, infected cases are always reserved for the last. The rule, "clean" cases first, "infected" cases last, is an invariable one.

The patient after operation usually makes an uninterrupted recovery. In very serious

cases, however, certain complications are liable to supervene, the management of which will be incorporated in a future article. I wish to thank Dr. Keen for permission to describe the technique which is so strictly carried out in the Jefferson Clinic.

1703 WALNUT STREET.

*THE USE OF INTRAVENOUS SALINE INJECTIONS FOR THE PURPOSE OF WASHING THE BLOOD.\**

---

BY H. A. HARE, M.D.,

Professor of Therapeutics, Jefferson Medical College.

---

I desire to call the attention of this Society to-night to the use of intravenous injections of saline fluid for the relief of threatened or present toxemia arising from renal disease, diabetes, or any acute infection, whether it be the specific micro-organisms which cause the eruptive or other fevers, or septic infection. My own experience is limited to its use in uremia and in toxemia associated with gangrene.

The use of intravenous injections for the relief of the collapse following severe hemorrhage or injuries is too well recognized as a valuable remedial measure to need any attention at this time. Surgeons resort to it or to hypodermoclysis, or the injection of saline fluid beneath the skin, quite frequently, and these means of resuscitation have practically displaced the obsolete practice of blood- or milk-transfusion. I believe that both plans are resorted to less frequently than is well, particularly the intravenous injections. The fear of an air embolus restrains some, I think needlessly, and the opening of a vein is as timorously performed now as it was boldly made sixty years ago.

The use of intravenous injections for the purpose of washing the blood is however an entirely different matter, one of very much more recent employment, and exceedingly popular with physicians on the European Continent, particularly in France. Within the last year almost every French journal has contained accounts of cases of toxemia treated with more or less success in this manner, and the results have certainly been such as to deserve wide trial and careful study. It is now a number of years since Stadelman proposed and used the intrave-

nous injection of carbonate of sodium for the relief of diabetic coma. This proposition, however, rested upon quite a different basis from that I am now discussing, namely, to antagonize chemically the acid which he believed to be in the blood as the cause of the diabetic coma. We now know that little if any permanent benefit results from such treatment, but that temporary improvement sometimes occurs. Thus Von Noorden speaks in glowing terms of one case of this character in which very good results ensued. Whether the good results which have been recorded were due to the chemical effect, or to washing the blood of impurities, is doubtful, but I am inclined to believe that the fluid entering the vein is responsible.

Before stating my own cases I shall take a few moments to cite illustrative cases from French and German sources:

Maygrier, apropos of a case of placenta prævia successfully treated by three intravenous injections (amounting to six liters) in one evening, says the reservoir of the solution is placed half a meter to a meter above the vein, and all air is carefully expelled from the tube and needle before the latter is introduced. Should the reservoir be lowered by mistake, blood may enter the cannula, clot there, and a clot be injected when the reservoir is raised. If any blood enter the cannula the instrument must be withdrawn and emptied, and the operation recommenced. The entrance of a small quantity of air does not matter.

Lejars exhibited a young man whose ruptured intestines he had sutured after peritonitis was fully established, and who recovered after receiving twenty-six liters of saline solution in intravenous injections; and gave details of three other remarkable cases of surgical infection cured in a similar way. He said that, always providing the kidneys are sound, such injections even in desperate cases have unhopd-for success, and should be generally adopted. Grave and threatening infection may be arrested or attenuated by one large injection, but it will generally be necessary to continue the lavage for some days, to use many liters of artificial serum, and to supplement the intravenous injections by hypodermic injections of moderate quantity every two hours.

Chasserany reported that he had found from experiment voluminous injections (intravenous, intraperitoneal, or subcutaneous) prevent the intoxication of rabbits by strychnine, provided they are made before the onset

---

\* A paper read before the Philadelphia County Medical Society, March 24th, 1897.

of the nervous symptoms, but Delbet was not able to detect the alkaloid in the urine or saliva of dogs poisoned by strychnine, and in one case only of eight was the effect of the poison modified by the injections. A dog of forty-three kilos received three milligrammes of sulphate of strychnine; then, in eighty-five minutes, 910 milligrammes of the saline solution; all symptoms ceased and the animal recovered. In 105 minutes from the beginning of the injection the enormous quantity of 532 grammes of urine had been passed. The animal was killed some days later by the same dose of the poison in twenty-one minutes. Further experiments had proved that the injection of even large quantities of the saline solution did not cause trouble when the arterial pressure was normal, or even when it was artificially raised by atropine; this method may therefore be employed in certain pathological elevations of pressure—for example, eclampsia. Pressure lowered by copious hemorrhage is rapidly restored by the injection of even a less bulk than the blood lost, but not so rapidly by the hypodermic as by the intravenous method.

Tuffier has practiced intravenous injections, both for hemorrhage and for toxemia, in fifty cases, including two cases of tetanus (after preliminary bleeding), and found the first effect was to restore the normal arterial pressure and diminish the frequency of the heart's action; the second, to cause diuresis.

Proben, in a case of eclampsia, injected two quarts of the normal saline solution; the urine had been almost totally suppressed, with 100 per cent. of albumen, but within twenty-four hours the woman passed 109 ounces.

Berlin reported to the Société de Chirurgie the case of a woman who, three days after vaginal hysterectomy, showed such violent symptoms of sepsis that recovery seemed absolutely impossible. The belly was distended and painful, and there was very marked subnormal temperature and frequent vomiting. On the fourth day the patient seemed to be about dying, whereupon Berlin gave an intravenous injection of a little over a pint of artificial blood-serum, and shortly afterward repeated this injection, using not quite two pints. Marked cyanosis and increased gravity of symptoms followed at once, but shortly there was decided improvement and the patient recovered, being completely convalescent the twelfth day of her illness.

Segond stated that he had used injections

of artificial serum for four years in all major operations, and had been able to save many cases of severe hemorrhage by this means. He also stated that in cases of severe sepsis these injections were potent.

Monod had also had excellent results from intravenous injections.

Michaud (*Le Progrès Médical*, No. 2, 1896) gives fifteen cases in which this treatment was adopted, all in septic peritonitis following operation. Of these, five recovered. In one case, the patient being in imminent danger, 1000 grammes of artificial serum at 39° C. were injected, causing immediate rise of temperature of four degrees, and a slowing of the pulse. The serum was used during three days, at the end of which time the patient was out of danger, and recovered. A similar result was obtained after ablation of the Fallopian tubes, where several injections were used, together with irrigation of the peritoneum. The artificial serum of Hayem, or simply sterilized saline water, was used. Various accidents were noted—vomiting, pain in the side, plethora, and disturbance of the cerebral circulation. No later complications were observed. The method is excellent, but other means—drainage, irrigation, re-opening of the abdominal incision, and the free local application of ice—are to be used concurrently. Monod has had seven similar cases, with three recoveries. The effects were beneficial, even in the cases which ultimately terminated fatally.

In the *Journal des Practiciens* of January 23, 1897, Bovet and Huchard first review the literature as to the employment of subcutaneous injections for toxemia, and then report an interesting case of pyelonephritis occurring in a married woman who had been a sufferer for a long time from a mild albuminuria. The patient became seriously ill from general toxemia, fever developed, the urine became scanty and albuminous, the tongue was dry, and a large number of casts were found in the urine. The pulse rose to 130; respirations to 28. Under these circumstances it was considered wise to inject a considerable quantity of normal salt solution. The authors publish a table and a temperature chart showing the course of the case.

The treatment began on the 20th of April and ended on the 15th of October. During this time the patient received injections subcutaneously twenty-five times and by the rectum about twenty times. The quantities injected under the skin varied from three ounces to two quarts a day, and the urine

made corresponding increases with each large injection. The table which they give not only includes the quantity of the injections, the quantity of urine in twenty-four hours, the amount of salt given each day, but also the amount of albumen, pus, leucocytes and casts, and the general symptoms which the patient presented during the time she was under treatment. They also report a second case in less detail in which there was uremia with general anasarca. As a result of this treatment they believe that hypodermoclysis is an exceedingly valuable procedure.

Usually as the injection is given the patient at once shows signs of improvement, but in from two to thirty minutes he develops a severe rigor with strong, rapid pulse, followed in half an hour by great flushing of the skin and then a profuse sweat, with greatly increased urinary secretion. Sometimes quite a marked febrile movement takes place. Several hours after the patient reports himself as greatly improved.

My own cases were as follows:

A man of sixty-odd years developed acute toxemia with high fever and coma, owing to the sudden spreading up the leg of a gangrene of the toes. At first he could only be roused by speaking sharply to him; later he became still more comatose. His muscles became spastic. Twelve hours after the onset of the toxemia I injected about one quart of warm normal saline into a vein on his arm in the course of an hour. He developed a severe rigor, then broke out in a profuse sweat, and next morning, ten hours after, was perfectly conscious, said he felt first-rate, but later in the day became comatose again and died. He was doomed from the first because of his gangrene.

The second case is that of a man with chronic parenchymatous nephritis, who came into the hospital with twitching of his muscles, and semi-comatose. He had passed scarcely any water for several days. Had had constant headache for six months. Was markedly edematous from head to foot. He was too weak to be bled, or to be purged, or to receive pilocarpine, and seemed too ill for a sweat from a hot pack. I injected one quart of hot saline into a vein of his arm. He also had a mild rigor followed by a sweat, and in three hours thirteen ounces of urine were obtained from his bladder. The next day he said he had no headache, no dizziness, no pain anywhere, and felt no discomfort. His dropsy was not increased. Ten

days later, as his uremic condition seemed to be returning, I repeated this injection, with similar results.

The apparatus which I use is constructed as follows, and embodies all that is necessary for the treatment of these cases:

A glass container such as is used for irrigation purposes in antiseptic surgery is set in a frame in order that it may stand on a table rather than be hung against the wall. To the bottom of this container is attached four or five feet of red Para rubber hose, and in the end of this rubber hose is inserted a plain glass cannula; a clip is placed upon the hose in order that the flow may be controlled, and the cannula and tube which have been attached to the blood-vessel are joined to the tube running from the irrigator at the moment when they are both completely filled with liquid, so that no globule of air will be contained in the tube.

We may next consider the best fluid to use. The following letter by Edes in the *Boston Medical and Surgical Journal* of March 4, 1897, embodies my views exactly. I shall use the formula herein described hereafter, although in the cases just detailed I had to use ordinary saline solution instead. Edes tells us that:

"A modification of Ringer's fluid has been in constant use in the Massachusetts General Hospital for about two years. The formula is 0.1 gramme CaCl, 0.75 gramme KCl to 1000 Cc. normal salt solution. This fluid has been used chiefly for intravenous infusion, by means of a cannula, in quantities of 500 to 2000 Cc. Its use in the Massachusetts General Hospital started from a suggestion made to the writer in 1894 by Dr. William H. Howell, formerly Assistant Professor of Physiology in the Harvard Medical School, who was then repeating some experiments of Sydney Ringer. One set of these experiments showed that calcium salts are essential to the clotting of blood. Another set consisted in passing different fluids through an isolated heart (frog's), and observing the character of the beats and the length of time the beating was sustained by such fluid. Blood-serum sustains the beats well and for a long time. A solution of the albumens of the serum without salts does not sustain the beats well, nor does a simple normal salt solution. The addition of a calcium salt alone to the salt solution causes strong beats, which however are too prolonged, and therefore inefficient. The addition of a small amount of potassium chloride corrects the character of the beat,

and this combination, normal salt solution plus calcium plus potassium, will sustain heart beats as well and as long as blood-serum.

"The idea lay very near to supply such a fluid to the circulation in cases of extensive hemorrhage, in place of using simple salt solution, which, experimentally at least, does not sustain the heart so well. Ringer's fluid is 100 Cc. of a .75-per-cent. solution of sodium chloride saturated with calcium phosphate, adding 1 Cc. of a two-per-cent. solution of potassium chloride. This is not convenient for use in surgery, however, because the boiling necessary for sterilization precipitates a phosphate of calcium. This might possibly be evaded by sterilizing the ingredients, but in the Massachusetts General Hospital it was found more convenient to use the soluble chloride of calcium. The fluid can be made up in Florence flasks, which can be boiled and the fluid kept sterilized for accident work, and warmed for use by placing in a pail of hot water.

"The difficulty of comparing the action of Ringer's fluid with that of salt solution is extreme, as the cases where either is used show such tremendous variations in prognosis independent of any treatment.

"It seemed to the author when he first used the fluid intravenously in accident cases in the winter of 1894-95, that the effect was more permanent than that of salt solution. Two or three remarkable recoveries from hemorrhage and from shock have occurred with, and possibly because of, its use. It is possible that a modification like that of Dr. Locke, containing 0.3 gramme calcium chloride to the liter instead of 0.1 gramme, as used in the Massachusetts General Hospital, is more advantageous; and again it is possible that one percentage may prove better adapted for intravenous use and another for rectal. It is much to be desired that Ringer's fluid should receive an extensive trial, and if possible in such a way that its value compared to that of simple salt solution may be estimated."

I wish in conclusion to strongly urge the use of this method of treatment in the toxemias I have named. I am confident it is well worthy of wide application, and while not a serious operation it offers probably the only chance for a series of conditions almost always fatal. The recovery of a clear mind, the setting aside of oncoming coma, is only to be seen to have this method appreciated.

## AMYLACEOUS DYSPEPSIA IN NEURASTHENIA.

BY JAS. G. KIERNAN, M.D.,

Foreign Associate Member of French Medico-Psychological Association; Fellow of the Chicago Academy of Medicine; Lecturer on Forensic Psychiatry, Kent College of Law.

The nutritional element in neurasthenia seems, like that of insanity, to revert to the condition present in childhood. The insane, especially where insanity is an accidental factor in the life of the individual, preceded by states of exhaustion, not necessarily related to heredity, but very frequently the outcome of ordinary somatic disease, have a tendency to scorbutus and allied nutritional disturbances without adequate external exciting factors, as I pointed out nearly two decades ago.\* Underlying this condition are, of course, the disturbances of innervation of the salivary glands, of the gastro-intestinal system, of the liver, pancreas and kidneys, which interfere with proper digestion, assimilation and elimination, thus creating a series of interlacing vicious circles, either one of which has been regarded as the exciting factor of the whole constitutional disorder. From these results the displacement of intestines which were so frequently found in the insane by the older alienists, and of late by Glénard in neurasthenics, who charges these gastro-enteroptoses with being the cause of the neurasthenia. On the contrary, however, the stress to which the bowels and stomach had been exposed by the disturbances of innervation consequent on the nervous exhaustion which preceded acquired psychoses produced, as the older alienists recognized, these conditions. The insane are especially liable to gastro-intestinal disturbances resembling, as Griesinger long ago pointed out, those found in infancy. These, as in the child, are readily under the control of diet. By securing control of the diet formerly in the hands of the contractors I have been able to reduce the death-rate to one-fourth of what it usually was, and to one-tenth of that specifically due to diarrheal conditions.

The fact is generally forgotten that neurasthenia is, as a rule, an initial stage of almost all the acquired psychoses and of many neuroses. The so-called *paranoia acuta* of the Germans, the primary confusional insanity of Spitzka† and the French and American alienists, develops on nervous adynamia. It is a

\* *Journal of Nervous and Mental Disease*, 1878.

† *New York Medical Gazette*, 1880.

psychosis "which develops rapidly on a basis of cerebral exhaustion. Consciousness is blurred in parallelism with the conceptional disturbance, and the patients on recovering have as a rule but very crude recollections of their condition. Its duration is variable, comprising weeks or months. The prognosis is as a rule as good as that of stuporous insanity, which condition it also resembles as to etiology; emotional shock, cerebral overstrain, exhausting diseases and excesses being the principal factors responsible for primary confusional insanity. The patients suffering from the psychoses, after a rapid rise of their symptoms during a period of incubation rarely exceeding a few days, present hallucinations and delusions of a varied and contradictory character. The delusions may resemble those of mania and more often those of melancholia, but no emotional state is associated with them. The patients assert in the same breath that their property is being stolen and that they are going to take part in some state affair. There is a surface resemblance between the confusion of mania and that of acute confusional insanity. The confusion of mania is not the expression of a genuine confusional state, but of a disparity between the ideational items and the word-channels through which they seek exit. That of acute confusional insanity is an expression of a true essential confusion of ideation."

This adynamia is a peculiar condition of the entire organism, a nervous asthenia, most obviously improved and benefited by stimulants in the food sense. The nervous system is the first part visibly affected, the heart the second; the contractile power fails, not from want of blood as in anemia, but more from shock or some toxic influence. The capillary activity seems impaired, the metabolism and nutrition thereby diminished; the contractile power of the heart and the blood-pressure being much decreased. This condition appears in acute and chronic forms of disease alike, partly as the main lesion, partly as a complication. Adynamia may cause many various disorders where foods have a distinctly beneficial action—headache, neuralgia, dyspnea, syncope, spasms, paralyses, etc. Individual causes may have a depressing influence on the general system, from emotion, as intense grief, joy, terror, shock, lightning, electricity, overwork, excessive intellectual toil, domination of violent passions, protracted anxiety and distress of mind, exhausting and prolonged diseases, foul air, etc.

This adynamia may proceed into neurasthenia, localized in the spinal cord and affecting spinal territories in such a way as to simulate organic disease, or it may take a similar course in regard to cerebral territories, or it may assume the type so generally recognized as neurasthenia with its morbid fears, its alternation between emotional depression or exaltation, its helmet sensation, its insomnia, its vertigo, or its disturbances of orientation. Neurasthenia is preceded by states which interfere with proper secretion in the glands concerned in digestion, and noticeably with those concerned in digestion of starch, whose secretions are altered in quantity, quality, or both. Recognition of the necessity for dietary regulation is general, but the method of regulation is very contradictory. As the evil influence of uric acid leucomaines is generally recognized, the supply of animal nitrogenized food is usually limited, and on the other hand the supply of starch and sugar, as well as the vegetable proteids, is increased. The principle here recognized is from a chemical standpoint seemingly correct, but from a biochemical decidedly erroneous. The interference with the starch-digestion glands already indicated has left a deficiency in the organism which will aggravate the existing condition if the excess of starch be given. Through this error often occur the distressing phenomena resultant on fermentation which so frequently annoy neurasthenics and underlie the creation of morbid fears. If the indication be clear that a proper supply of starchy food be needed to break up that monotony in diet which plays such a large part in metabolic disturbance, then as the absorptive powers are all right the digestive factor should be assisted. These two conditions are recognized, but although the proteid is cut down, it is assumed of necessity that indigestion exists only as to it; and therefore pepsin is given, albeit starchy material is poured in in greater quantities than in health. The fact is that while starch undoubtedly is indicated in neurasthenia, power of its digestion is interfered with, and requires assistance. In these cases a remedy seems needed whose quantity will be minute and which will act rapidly. The agent that I have found excellently adapted in most cases has been Taka-Diastase. This has no contraindication from the bulk of dose, is readily given with meals, and in the quantities needed is exceedingly economical. It tends to diminish retrograde metamorphoses in the intestine and hence destroy the undue accu-

mulation of gas which is so unpleasant and distressing to the patient, in both its subjective and objective aspects. One great recuperative factor in the treatment of neurasthenia is diet, and one great difficulty in the way of proper diet is constituted by the mental and physical effects resultant on monotony. The elements in diet which would prevent this monotony are such as are logically contraindicated because of the interference with their digestion by the digestion innervation disturbances consequent on the disease.

As a rule these disturbances largely involve amylaceous digestion and hence require agents like Taka-Diastase for their assistance. This agent, while of no value in the treatment of nervous exhaustion considered as a neurosis, is of very great service in securing the proper dietary care of these patients, which plays such an enormous part in the recuperation of their nervous systems.

#### VENESECTION.

KRÖNIG (*Berliner Klinische Wochenschrift*, Oct. 19, 1896) begins a study of this subject. He refers to the authorities who have recently advocated venesection in certain cases, and first discusses its use in acute pneumonia. The effect of edema of the lung, or a very massive exudation compressing the capillaries, is such as to cause an insufficient exchange of gases, thence a CO<sub>2</sub> intoxication. With this is associated a mechanical difficulty. For a time the reserve force of the right ventricle can overcome these difficulties, but when exhaustion sets in there is dilatation, and then commences the danger to the patient. The blood is driven into the left auricle with difficulty, and the heart muscle is insufficiently nourished. The pressure in the pulmonary circulation increases, and that in the aorta diminishes. To overcome these dangers recourse is had to two expedients, namely, (1) to increase the power of the right ventricle by stimulants and cardiac tonics; and (2) if this does not succeed, to reduce the mass of the blood by venesection. Often venesection then produces a diminution of the cyanosis and of the dyspnea, and the pulse gains in strength. The author believes that the best time for venesection is near the time of the crisis. It should be repeated if necessary. He refers to three apparently hopeless cases in which venesection was followed by recovery. Again, in non-febrile affections of the heart and lungs the pul-

monary circulation may become overloaded. Here venesection may give even better results than in acute pneumonia. Occasionally in heart disease sudden exhaustion may occur in a heart hitherto acting relatively well. Cyanosis, smallness of the pulse, intermitting respiration, may lead quickly to death. By a venesection the right heart is relieved. The author refers to two such cases. One occurred in a man aged fifty-eight, who was seized with sudden and most severe dyspnea. After bleeding to 200 cubic centimeters the cyanosis rapidly disappeared. In the other case a girl aged sixteen, with heart disease, was suddenly seized with great cyanosis. The radial pulse could not be felt, and there was Cheyne-Stokes breathing; 380 cubic centimeters of blood was withdrawn, camphor injections given, and artificial respiration practiced. On the following morning there was no trace of the severe symptoms of the day before. There is a group of cases in which the cardiac tonics do not act satisfactorily. The author refers to one case in which the patient appeared almost moribund. Digitalis failed to relieve him until venesection had been performed, when it yielded the best results, and the patient lived for two years.—*British Medical Journal*, Nov. 28, 1896.

#### THE ACTION OF SULPHATE OF QUININE AS AN OXYTOMIC.

SCHWAB in the *Journal de Médecine de Paris* of November 29, 1896, points out the value of quinine as an oxytomic, thereby emphasizing a fact already well known to American practitioners. He believes that it is of great value in ordinary uterine inertia and in all cases where we have reason to believe that the uterine contractions are or will be feeble. He cites a number of cases in which the administration of full doses of quinine under these circumstances produced the most happy results, and he notes a number of French authors whose experience has agreed with his own. In the discussion which followed his paper the question arose as to whether quinine administered to pregnant women was capable of producing abortion. That this danger exists seems, however, to be largely imaginary, and the drug can be given whenever indicated in moderate doses to pregnant women prior to full term with perfect safety. This result is also in accordance with what we believe to be the general conclusion of American practitioners.

### QUININE IN MALARIAL HEMATURIA.

There is still great difference of opinion between physicians of wide experience as to the value of quinine during an attack of malarial hematuria, it being held by some that it is almost a specific, while others are equally positive that it is contraindicated by this condition. In this connection it is interesting to notice a report made by Robertis, an Italian investigator, an abstract of whose paper was published in the *Deutsche Medizinische Zeitung* of June 15, 1896.

This clinician relates the case of a patient who, after having suffered from two paroxysms of malarial fever, received twenty-five grains of quinine in the course of a few hours, the quinine being given for the purpose of preventing another attack. A few hours after the last of the quinine had been taken he had a severe chill followed by fever, cyanosis, and headache, and the urine became bloody. This was followed in the course of twenty-four hours by jaundice and swelling of the liver. Two days after these symptoms the patient, being entirely free from fever and thinking

himself about well, took twelve grains of quinine in three doses, when he suffered from another chill and its consequent symptoms, the urine also becoming bloody.

This case is of considerable interest because it is practically identical with a number of other cases which have been reported in American and foreign literature, particularly by Greek and French writers.

In a collective investigation upon quinine in malarial hematuria, published in the GAZETTE in 1892, the writer of this editorial quoted from the opinions of a number of practitioners. Karamitsas of Athens, in the *Bulletin Général de Thérapeutique*, reported seven cases of hematuria due to quinine, one of them being in a child and the others in men, and curiously enough six of the individuals were medical men. In all these cases he was able to produce hematuria at will by the administration of quinine, and further he found that they passed through the malarial paroxysm without hematuria if quinine was withheld, but developed hematuria if this drug was given. Tommasselli has also seen similar cases, as has also Carreau. Finally Pampoukis and Chomatianos of Athens have reported cases in which quinine caused hemaglobinuria, the salt most frequently producing this symptom being the sulphate.

The conclusions reached in the collective investigation which we have quoted and which it may be permissible for us to mention, considering the fact that they were published some years ago, were that quinine should not be employed in the milder forms of malarial hematuria nor in those cases in which idiosyncrasies to its action exist. On the other hand, in those cases which are malignant in their manifestations in other lines than the mere hematuria and dependent upon a malarial paroxysm superimposed upon a malarial idiosyncrasy, then quinine is needed. In that form of hematuria following prolonged or subacute malarial poisoning, quinine is not to be given in full doses but only as a tonic. The general trend of the information gained in this collective investigation is rather against than for the administration of quinine to combat this condition, for its use in full doses in the presence of hematuria is equivalent to locking the door after the horse is stolen. Hematuria may be considered the result of a malarial paroxysm, and the use of quinine after this symptom has developed is equivalent to its employment after the harm has been done.

### THE DIET OF TYPHOID-FEVER PATIENTS.

The question as to the proper diet for patients suffering from enteric fever is one that has been considered settled by the medical profession in general, and it seems to be the almost universal opinion to-day that coincident with the diagnosis or suspicion of typhoid fever we should exclude all solid articles from the patient's diet list, insist that he shall partake of liquid foods only, and rely chiefly if not entirely upon milk.

Against this pure milk diet there are of course four objections which can always be urged with considerable force: First, a diet limited to any one variety of food is not, as a rule, particularly advantageous but rather disadvantageous to the individual both in health and disease; second, milk disagrees even in health with a considerable proportion of otherwise healthy patients; third, the patient is required to take a large amount of liquid in proportion to the nourishment which he obtains, which perhaps is not so great a disadvantage in that it tends to flush the kidneys; fourth, milk very frequently produces, as is well known, a large amount of gas in the bowel, and should constipation be present as a symptom of typhoid—and it certainly is frequently present notwithstanding classical descriptions to the contrary—this diet will increase both the tympanites and the confinement of the bowels. We confess that it is our custom to resort to a rigid milk diet in all such cases, but our attention has nevertheless been called to and interested in an article by Dr. A. G. Barrs, Professor of Therapeutics in the Yorkshire College of the Victoria University in England, which he has contributed to *The British Medical Journal* of January 16, 1897.

In this article Dr. Barrs inveighs against the insistence upon a rigid milk diet and advocates the administration of solid food both during the acute stage of the disease and during convalescence. He asserts, somewhat dogmatically perhaps, that there is no good evidence that solid food is always contraindicated; but at the same time he points out that, in his opinion, our guide in the administration of food to patients suffering with this disease is, to a certain extent, the desire of the patient, provided his mind is clear and he seems qualified to make a sensible statement of his needs.

In Dr. Barrs' experience a patient unable to digest meat and other materials of a simi-

lar character, during the early stages of typhoid, is usually too sick to ask for or even to desire solid food, and he does not believe that a person with a dry and sordid-covered mouth and parched tongue and all the evidences of marked asthenia would have any desire for, but rather an abhorrence of, eatables in general. In other words, Dr. Barrs says that "whenever a typhoid-fever patient can eat meat and enjoy it" he is never in much doubt as to his recovery, and he does not think that solid food, provided it is not so solid as to be indigestible, in any way increases the danger of hemorrhage or perforation in typhoid fever. But he evidently believes that the diet, like the treatment, should vary with the symptoms of the patient and not be resorted to in a purely routine manner.\* His chief object in urging this method is that during the course of typhoid fever the patient needs all the concentrated nutriment that he can obtain, and that a semi-solid or solid diet aids him in its acquirement. On the other hand, it is well for us to remember that in typhoid fever the digestive juices of the entire alimentary canal are so altered in their constitution that under many conditions it is doubtful whether solid food could be digested. It is a fact well known to physiologists that fever arrests the secretion of normal gastric juice, and as this is the case, surely the digestion of meat, even if it was finely chopped up as suggested by Dr. Barrs, could not be carried out.

### THE ABSORPTION OF DRUGS.

One of the most important factors in successful medication is the administration of drugs which are easily dissolved in the stomach or intestine and afterwards easily absorbed. In many pressing cases time will be lost if insoluble substances or drugs that are slowly absorbed by the gastric mucosa are administered in place of those which can rapidly enter the blood-stream, and in many instances physicians are prevented from administering remedies which are otherwise indicated because these remedies lend themselves so slowly to the process of absorption. Probably with greater frequency the physician is brought face to face with the fact that while the drug is soluble and easily absorbed under usual circumstances, in this particular instance the stomach of the patient is in such an abnormal condition that it is incapable of carrying out its physiological

function, and that remedies which are placed in this viscus remain unabsorbed and, in consequence do not produce any effect, at least for many hours. Quite frequently we believe that the excessive effects which sometimes follow the repeated administration of remedies depend for their existence upon the fact that the inactivity of the stomach has not been recognized, and that repeated doses have been given until after a number of hours the stomach returns to its wonted activity and the total amount of medicine administered over a considerable period of time enters the blood-stream in one mass. It is quite in the power of the physician, however, in many cases, if he is skilful enough to recognize the fact that the stomach is inactive, to stimulate it to the performance of its proper functions by combining with the drug which he most desires to administer another remedy which by reason of its stimulating influence will cause the stomach to produce its normal secretion and carry on absorption. We refer particularly to the administration with ordinary drugs of such substances as capsicum or its oleo-resin, or mustard and ipecac, all of which act as powerful stimulants to the gastric mucous membrane. Or if it is thought that the stomach is in a condition of nervous excitation and yet incapable of absorption, we would suggest the administration of chloroform water or spirit of camphor. By the combination of these remedies with such a drug as digitalis, for example, we quickly obtain the influence of a cardiac tonic through the aid of the gastric stimulation.

#### LIMITATIONS OF EXTIRPATION OF THE KIDNEY.

With a more detailed knowledge of kidney affections, with improved technique, and, at least in so far as the reported cases are concerned, with lessened mortality for total excision, the operation of nephrectomy for various pathological conditions of the kidney is becoming very much more popular. This operation is based upon a belief that one kidney can be removed without seriously affecting the health of the other, the remaining one serving to eliminate a sufficient quantity of urine.

In this relation a recent communication from Wagner (*Centralblatt für die Krankheiten der Harn- und Sexual-Organen*, bd. viii, heft 2, 1897) is particularly important. It has been clearly shown that in case of congenital atrophy of a single kidney the remaining

organ undergoes a process of overgrowth enabling it to take the place of the absent organ. Although it has often been asserted that this also occurs when the organ is extirpated after partial or complete systemic development, there are now a sufficient number of cases which have been subjected to careful examination to prove that such a rule is subject to many exceptions, and that the remaining kidney is sometimes unable to take upon itself the functions of both.

Such a post-operative insufficiency often develops when least expected—that is, when there is every clinical evidence to show that the remaining organ is healthy. The true basis of this insufficiency seems to depend upon a bilateral crippling. It has been proven that long continued suppuration of one kidney, whether it be due to calculi or to other exciting causes, often leads to an undemonstrable chronic parenchymatous and amyloid degeneration of the other kidney, and hence to a suddenly developed insufficiency when the obviously diseased organ is removed.

Israel has also shown that even though the remaining organ be healthy, following operation, an ascending infection from the bladder is prone to develop.

In other cases although the remaining kidney is healthy there develops in it, following unilateral nephrectomy, a coagulation necrosis which destroys the secreting epithelium and shortly leads to insufficiency and death. The cause of this parenchymatous nephritis is said to depend upon the influence of narcotics and antiseptics, especially chloroform, carbolic acid and iodoform.

Exceptionally following nephrectomy fatal anuria develops, although macroscopic and microscopic examination of the remaining kidney show no pathological alterations. The inhibition of secretion is in this case probably reflex and of a similar nature to the anuria which develops in consequence of unilateral ureteral obstruction by a stone.

It is also obvious that in case of unilateral absence or shrinkage of the kidney removal of a single secreting organ would be followed by anuria. The possibility of such a congenital deformity must always be considered before deciding upon extirpation of the kidney. Morris found from a study of over 20,000 autopsies that this congenital malformation occurred once in 318 sections. Ballowitz has collected 213 cases of single kidney and finds that in man the left kidney is generally absent; in woman the anomaly is equally fre-

quent on both sides. It is about twice as frequent in men as in women.

The possibility of fusion of the kidney must also be considered, since operation under such circumstances is necessarily fatal unless the condition is recognized.

Socin and König have, however, operated on a horseshoe kidney, dividing the band of connection without serious hemorrhage and removing the diseased portion. Braun under similar circumstances was deterred from completing his operation by uncontrollable venous hemorrhage which was followed by death.

Practically the only method of recognizing abnormalities of formation or position of kidneys is by exploratory incision. All other diagnostic means are unsatisfactory. Even cystoscopy and catheterization of the ureters may fail. This is especially the case in horseshoe kidney, since usually there are two ureters opening into the bladder in the normal position. In other cases of fusion double ureters are frequently observed. Indeed the ureters may be multiple.

Congenital absence of one kidney is commonly accompanied by absence of the ureter and of the corresponding portion of the vesical triangle, although this rule may have many exceptions. In women congenital absence of one kidney is often shown by unilateral abnormalities in development of the sexual system.

In addition to the dangers already mentioned which are attendant upon nephrectomy, it cannot be denied that when the organ is deeply placed and adherent to surrounding parts its removal is one of the most difficult and dangerous procedures known to modern surgery.

In the operations undertaken for the removal of malignant growth or tuberculous infiltration, cases should not be counted successful simply because the patient recovers from surgical interference. Even with a perfectly healthy, properly compensating kidney such a patient is more vulnerable than one provided with two kidneys. Autopsies have shown that more than one-half the cases of congenital absence of the kidney showed some disease of this organ, and the majority died because of such disease. Such kidneys are particularly subject to stone. The single kidney remaining after nephrectomy is even more vulnerable.

Schramm has reported a case in which he removed the kidney of a 25-year-old woman because of hydronephrosis. Four years later

she became pregnant and up to the fifth month suffered from polyuria and albuminuria, and later there developed an irregular heart action. This patient recovered, although she was slow in convalescing. The author concludes that under such circumstances—*i.e.*, when one kidney has been removed—future conception should be prevented.

It is evident from what has preceded that a kidney which is functionally sound should never be sacrificed; the diseased kidney should only be removed when the nature of the disease and its extension are threatening. Kidney diseases which more conservative methods may cure, even though these require a long period of time, should not be subject to nephrectomy, since even a very small portion of secreting substance may be a vital necessity to the system.

In the vast majority of kidney diseases nephrectomy can advantageously be substituted by nephrorrhaphy, nephrotomy, partial resection, resection of the ureters, implantation of the ureters, or other procedure. Nephrorrhaphy is the operation for wandering or displaced kidney. Nephrolithotomy should be employed in all cases of stone when the latter has not led to profuse suppuration and extensive destruction of kidney substance. Nephrotomy is sufficient in the majority of cases of kidney suppuration and of hydro- and pyonephrosis; also for the relief of solitary cysts of the kidney or of echinococci. Partial extirpation is indicated in the rare cases of non-malignant tumor, of suppuration, concrement or cyst formation. In the case of fistula, if the kidney is sound resection should be replaced by a plastic operation upon the ureter.

Nephrectomy may be primary or secondary. Primary nephrectomy is indicated in cases of malignant growth, either from the kidney itself or its capsule. The mortality in eight years has been extraordinarily diminished, probably because of increased skill in diagnosis and improved technique, though it is rare the true nature of the affection is detected early. Exceptionally hematuria and pain will justify an exploratory operation through a unilateral or bilateral lumbar incision. Under such circumstances nephrectomy promises well. Very exceptionally repeated examinations of the urine show fragments of a tumor.

Palpation of the kidney, if carefully conducted, sometimes will enable the surgeon to make an early diagnosis. Israel showed this in four cases, the accuracy of his diagnosis

having been confirmed by operation. At the present time a tumor growing over the upper segment is practically inaccessible, and Rovsing states this is the region of the greater number of these tumors. Seventeen cases were collected by Wagner in 1893 in which the patients lived from one to six years without recurrence. Those who remained free from recurrence for two years may be regarded as cured, since later rescidivity is unusual. There are exceptions to this rule, as in the case contributed by Rovsing in which there was recurrence after three years.

An examination of over a hundred cases of nephrectomy for malignant growth shows that in the great majority of cases there is recurrence or metastasis within six months; that these accidents are progressively less frequent with the lapse of time, and with few exceptions are not observed at all after two years. As to the direct results of operation for malignant growth of the kidney, the mortality has been diminished from 61.22 to 24.40 per cent.

---

## Reports on Therapeutic Progress

---

### *THE THERAPY OF DIPHTHERIA OF THE CONJUNCTIVA AND TETANY.*

The serum or antitoxin treatment of pharyngeal and laryngeal diphtheria has taken an unassailable place in the therapeutics of this disease, and we now look for reports of its utility in the treatment of diphtheria manifesting itself by the deposition of membranous formations in other parts of the body, such as the conjunctiva. Very recently some statements worthy of note have been made anent such conditions by GREEF. He treated after this method fifty-two cases of genuine conjunctival diphtheria, with the very gratifying result of seeing thirty-seven of these cases recover. In only two did death result. This is a percentage that has scarcely been equaled. Naturally in conjunctival pseudo-diphtheria the serum treatment is of no use, but it is a matter of importance to bear in mind that the author avers that such treatment does no harm, particularly when we recall that Guttmann claimed that a greater proportion of cases of diphtheria were followed by polyneuritis when subjected to antitoxin treatment than when treated in other ways. Greef was unable to draw any conclusions as to the effect of the serum treatment on the course of the paralysis that so often follows diphtheria on

account of the relatively small number of his cases. He does say, however, that he has not noticed the more frequent occurrence of neuritis in cases that have been treated with serum. We expect to be able to publish within a few months a report on a large number of cases of diphtheria to show that the antitoxin treatment, instead of conducing to the occurrence of multiple neuritis, not only does the opposite but has a most benign influence upon this condition when symptoms of neuritis appear early in the disease.

In this country at least tetany is not a common condition. We believe, however, that its occurrence is more frequent than the scant literature of the subject would lead one to believe. This is so because, in all probability, a number of cases in which the symptoms are comparatively slight go unrecognized, while others are diagnosed as "fits" or "spasms." The nature of tetany is still a matter of active dispute, the most universally accepted view of its causation being that it is a neural or neuro-muscular manifestation of some hemic poison of endogenous or exogenous origin. Comparatively few writers have subscribed to the views of Kassowitz and others that it is a cerebral manifestation of rachitis, analogous to laryngismus stridulus, for it is believed that such a view is opposed not only by experience but by the tenets of modern pathogenesis. It seems to be very probable that the toxic substance that causes the symptom tetany is absorbed from the stomach, and that it is formed as the result of functional derangement of that organ or of organic disease. It is a well known fact that the most fatal form of the disease is associated with a peculiar destructive process in the walls of the stomach. Added to this there may be some special vulnerability of the nervous system analogous to that existing when chorea develops from some humoral poisoning. Oddo has recently asserted that the contention of many German writers that laryngeal spasm is pathognomonic of tetany is a fallacy. It may occur just the same as spasm of the ocular muscles and stiffness of the muscles of the neck occur, but it is no more pathognomonic of this condition than the latter are of meningitis.

In the treatment of tetany this writer does not suggest anything new, but basing his therapeutic suggestions on the modern conception of the disease he recommends the removal of the toxic factors by means of stomachic and intestinal lavage; and at the same time he administers substances that

contribute to a condition of the intestines that is at least inimical to fermentation and putrefaction, such as small doses of calomel and benzo-naphthol in one-half grain doses five or six times a day. If there be any indication for the use of vermifuges they should be given. The peccant activities of the poison on the neuro-muscular system are counteracted by the administration of bromide of strontium and chloral. In our estimation bromide of strontium has no superiority over any of the other bromide salts, and the chloral is the most efficacious factor in the combination. We are glad to note that this author recommends the use of chloroform to cut short the tetanic condition when it becomes very severe.—*Pediatrics*, Dec. 15, 1896.

---

**CONTRAINDICATIONS OF SALICYLIC  
TREATMENT IN ACUTE RHEU-  
MATISM.**

JACCOUD (*La Semaine Médicale*, Oct. 28, 1896) holds that the beneficial action of salicylate of soda in acute rheumatism is confined to the joint affection, and has no effect on the visceral complications. He never prescribes it where there is endocarditis; in pulmonary complications it increases the dyspnea, promotes the appearance of albuminuria, and when there is headache, delirium, or other cerebral phenomena, might entail the patient's death. In the more common form of rheumatism in which the visceral complications are of moderate intensity and do not show till the second week, it is not unusual to meet with a sort of alternation in the severity of the arthritis and the cardiac or pleuro-pneumonic affection. Salicylate of soda, he believes, in relieving one aggravates the other, and to a proportionate extent. He quotes statistics of Donald Hood, S. Coupland, G. Smith, and Bodt, to show that visceral complications are more common in cases treated by salicylates of soda than in others, and concludes it ought never to be given when such complications exist.—*British Medical Journal*, Nov. 28, 1896.

---

**A FEW PRACTICAL HINTS TO MEDICAL  
MEN ON THE PRESERVATION OF  
THEIR OWN HEALTH.**

In the *British Medical Journal* of December 19, 1896, was published an address delivered by Mr. JOHN M. TEALE on this subject before the Leeds and West Riding Medico-Chirurgical Society. He began by saying that he pro-

posed to offer a few practical suggestions as to how each of us may do something to take care of his own health, which is of some considerable value not only to our families and our patients, but to ourselves. In reading the addresses delivered to students at the opening of the October Sessions one is often struck by the vast variety of suggestions that are made as conducive to success. But were the author asked what, in his opinion, would most conduce to the success of the general practitioner, he should say power of concentration and command of temper.

By power of concentration he means that power by which a man, however wearied, on entering a house is able instantly to abstract his brain from everything that has gone before, and to concentrate his mental faculties on the case that is before him. Patients are naturally somewhat selfish, and are very quick to observe if they do not get full attention, and if, when the finger is on the pulse, the mind is with the patient who preceded him.

Secondly, command of temper. To the quick, high-strung, sensitive man, exhausted by the worry and anxiety of daily life, thorough command of temper with testy, querulous, exacting patients can only be obtained by rigid self-control commenced in early life. To be forever bearing in mind that the patient is the sufferer, that testiness and ill-temper are due to physical weariness and distress, and not to disloyalty to the doctor, is a task that will try the strongest nature.

If, then, concentration and command of temper are essential to success, how can they best be cultivated and obtained? Surely by living as far as possible a simple, healthy, outdoor life, in constant physical training. Young men nowadays, as a rule, at some period of their student life pass a year or two in a high state of training; but how many of them, amid the worries and distractions of a busy practitioner's life, keep up that condition of training to mid-life, still less to old age? Why should a man become stout and short of wind because he has reached fifty? Simply because he is struggling with his life-work when his physical condition is not fit to grapple with it.

The whole subject of physical training and its usefulness in moderation was brought prominently before the writer in his Oxford days by the late Archibald McLaren, whom he looks upon as the pioneer of modern and rational gymnastics. He well remembers

being selected as one of three lightweights, in conjunction with several heavyweights, to show off the new gymnasium to a squad of army sergeants from Aldershot under Major (now General) Hammersley, and how in a month they were sent back with largely increased biceps and largely reduced abdomens. This was the beginning of regular gymnastic training in the British Army, the results of which were seen at the military tournaments at Islington.

For two years also the author steered his college crew. It was then customary for the coxswain to take charge of the training of the crews, and he was expected to be in such training himself that he could take an oar at any time while the captain coached. The writer learnt then, and has never forgotten, what ease it gives to daily work to be in good condition, and has done his best to remain so ever since.

Assuming that a man is physically sound, and has cultivated athletic exercises in youth, it is quite surprising how easily that condition can be maintained provided only it be done regularly. He remarks that the "strong men" who exhibit in public rarely practice their feats in private, and rely on light dumbbells to keep them in good condition.

For most men light Indian clubs, or the Ranelagh, or exercises on both of them, carried out systematically night and morning, will do all that is needed. It is surprising what a rest, after a hard day's work, some active physical exercise with the arms will be found to be. It is a mistake to suppose that the busy man wants a great deal of physical exercise. His ordinary day's work, with what it involves in taxing mind and body, is generally nearly enough for him, with some physical exercises, as suggested. It is always well to have something in hand, for extra strain comes most unexpectedly. It is well to cultivate the art of sleeping for a few minutes at any time. A man can only live safely on the interest of his vital strength. Any withdrawal of principal should be promptly replaced.

For a sound man everything that is good is wholesome, taken at proper times and in proper quantities. One should teach his stomach to understand that within these limits every good thing well cooked is good for it. After a man is twenty-five or thirty he only wants as much food as will maintain his weight and not add to it. It is possible to be too busy to dine, in which case a cup of soup, or a sandwich and glass of wine, is

better than a hearty meal. A good dinner implies leisure for digestion. Half-an-hour's leisure before dinner will often enable a man to eat a hearty meal. For most medical men he believes a late dinner is preferable, for if taken in the middle of his work either the meal or the patients must suffer. The fewer the meals the better for health. Two good meals and a moderate one are enough for most healthy men leading a busy life.

Teale says: "Mix your wines by all means, provided they are good, and you do not take too much of them. Spirits are useful when jaded or exhausted as a change from wine at dinner, but are unnecessary and hurtful when taken between meals or at bedtime, except for special reasons; 365 glasses of whiskey taken in one year at bedtime are an unnecessary and severe tax on the liver when its work is in full swing."

An ordinary healthy man may have a cold bath daily almost up to any age, but as the object is not only to get up a reaction, but to keep it, most hard-working men require that cheapest of all luxuries, a fire, in the dressing-room, and a hot bath towel. If this is followed by a course of Indian clubs in his flannels, a man will be fit to face any weather.

The same underclothing should be worn summer and winter of wool, and only the outer clothing varied. Colds are generally caught either in ill-warmed rooms or through ill-protected feet. With good Jaeger boots and putties, as the serge leg-rollers are called which were introduced by the 10th Hussars from Afghanistan, one will be able, with a good overcoat, to drive with impunity in an open dog-cart in a blizzard, especially if one have laid in a store of caloric before starting, and by breakfasting in the wraps in which one proposes to travel.

Light your fire whenever you can endure it; it is the cheapest and best health-giver in the world, especially in cold, thundery weather in the summer. With a well-arranged room and a well-contrived fireplace, most healthy people can learn to sleep with their window open winter and summer.

Medical men are specially liable to badly aired beds, for they are often sent for hurriedly. Nor will the strongest constitution resist such an infliction. This risk will best be guarded against by carrying in your traveling-bag a light flannel dressing-gown to put on the damp sheets.

No medical man should ever have a bad tooth in his head. He is courting disaster if he does so. It is a simple matter to brush

the teeth after every meal, and by rinsing with cold water you get an early intimation of danger.

No amount of precaution can make turning out of bed at night otherwise than dangerous. But if an arrangement can be made by which the clothes can be kept aired and warm, and a cup of hot milk with a teaspoonful of brandy can be procured, the risks can be reduced to a minimum.

One word about holidays. Every medical man should, if possible, have an outdoor sport of some kind. Golf and cycling are good, but perhaps the best of all is fly-fishing. It takes one usually into beautiful country, the exercise is gentle and varied, the interest absorbing, and to the author's mind is far better for the jaded practitioner than scampering half over Europe in a hurry in a second-class railway carriage in charge of a party of tourists.

#### VALUE OF ANTITOXIN IN DIPHTHERIA.

We are told in the *Intercolonial Medical Journal* of Australia of October 20, 1896, by TURNER and ASHWORTH that the use of antitoxin serum injections has caused a large and altogether unprecedented fall in the mortality from diphtheria in the Brisbane Hospital for Sick Children.

This fall in mortality is especially noticeable among the cases in which laryngeal symptoms threaten to cause asphyxia. The proportion of cases recovering without operation has largely increased, and the total mortality has been reduced by three-fourths.

To obtain these results, it is necessary to inject very large quantities of the weaker serums hitherto commonly used in Australia.

No toxic symptoms of any gravity have been observed in any instance to follow the injection of even the largest amount given (50 Cc. in a single injection, or a total of over 100 Cc. in several injections).

The prolonged gradual convalescence observed after severe diphtheria has been in most cases replaced by a speedy return to health.

Both the serum supplied by the British Institute of Preventive Medicine, and that by the Höchst Fabrik under the supervision of Professor Behring, have been found effectual in the most severe cases, if injected in sufficient quantity. Behring's serum has the following advantages: (a) known antitoxin-strength; (b) greater concentration, so that it is sufficient to inject a much smaller bulk

of serum; (c) freedom from decomposition; (d) less frequent occurrence of urticarial rash.

These conclusions they base on careful clinical observation of the majority of the more severe cases of diphtheria occurring in Brisbane, both before and after the commencement of the antitoxin treatment. They have given their results in statistical form, as the only way of presenting them in a condensed and easily comprehensible manner. Though they have attempted to supplement the figures (which are too small for purely statistical treatment) by brief outlines of some of the cases, they are well aware that it is impossible to bring the full force of the clinical evidence before the readers. The effect on the writers' minds is this—that whereas formerly they regarded diphtheria as a most treacherous and fatal disease, over which medical treatment had little or no direct influence, and of which the mortality was inevitably high, they now regard it as a disease for which we have a perfectly reliable specific antidote. They are willing to admit that there may be, and probably are, malignant cases, with secondary infections from the first, which cannot be saved by the serum; but they have never seen any such cases, and they must be exceedingly rare. The fatal cases they have lately seen have all been ill at least four days, usually longer; and there is no reason for thinking that they could not have been saved by earlier treatment. There will always be a certain death-rate from diphtheria, owing to the postponement of treatment until it is too late. They hardly expect that their hospital mortality will be reduced below ten per cent., unless fewer moribund or advanced cases with secondary complications are brought in. But if the profession and public once grasp the truth that with rare exceptions no child ought to die of diphtheria, it is probable that the actual mortality will become very low.

But to attain this result much larger doses of antitoxin should be given than are at present in common use. The doses hitherto employed, as far as we can gather, are only suitable for the milder cases, or those taken within the first two days of the onset. By the use of serum of the high antitoxin value recently attained under the supervision of Professor Behring, there will be no difficulty in giving doses up to 4000 units. When serum of weak and undetermined strength is used, the only possible course in a severe case is to inject large quantities in repeated doses.

This the writers have done in hospital work, but it is not so easy in private practice. Indeed even in hospitals the use of serum of undetermined strength is to be condemned. It is unfortunate that the antitoxin treatment both in Australia and Great Britain has consisted to a large extent of the injection of insufficient doses (10 Cc. to 20 Cc.) of serums whose only comparative merit is their cheapness. In *The Lancet*, July 18, 1896, will be found a detailed report as to the strength of these serums. As serum of the highest concentration and of known strength is now easily obtainable, it is to be hoped that it will soon be recognized that the use of inferior preparations of unknown strength is not compatible with a conscientious regard for the interests of one's patients.

#### THE THERAPEUTIC USES OF CHLOROFORM.

We have never been quite able to understand why the use of chloroform to abbreviate all sorts of convulsive attacks—eclampsia of the infant, of the adult, genuine epileptic attacks, hysterical and toxic convulsive attacks, and even epileptiform convulsions dependent upon organic diseases of the brain—has not become more universal. It has three virtues that must commend it to every thinking practitioner: it does the work quickly and promptly, it is practically devoid of danger, and its use is not attended with distressing or malign after-effects. Why time should be wasted when one is called to a child or an adult in convulsions of an eclamptic nature, by putting them in a warm bath, or giving a rectal injection of chloral and bromide, or doing a half-score of other things that have nothing to recommend them except a halo of tradition and the consecration of inherited usage, is difficult to comprehend. An eclamptic attack, it matters not whether it be a manifestation of genuine epilepsy or not, is an evidence of the diminution in the potentiality of those structures one function of which is to subserve motivity, and a perversion of the dynamics of these parts. One attack of such eclampsia contributes to another just as the pathway of a man through a forest contributes to the ease with which he orients himself on a second visit to the same wilderness. It behooves us therefore to cut short every attack of this kind without ceremony, and the best way to do this is by the inhalation of chloroform, not necessarily up to the point of complete

chloroformation, but enough should be given to control the severity of the spasms. After that is the time to give bromides, chloral, etc. —*Pediatrics*, Dec. 15, 1896.

#### THE TREATMENT OF SENILE PRURITUS.

*L'Abeille Médicale* of November 28, 1896, gives the following prescription:

- ℞ Bromide of sodium, 2 drachms;  
Salicylate of sodium, 2 drachms;  
Acetate of sodium, 1 drachm;  
Infusion of gentian, 2 ounces.

A teaspoonful of this solution is given in water one hour after each meal, and when the pruritus is limited to certain regions the following solution is employed locally:

- ℞ Liquor potassi (6 per cent.), 2 drachms;  
Carbolic acid, 4 drachms;  
Linseed oil, 1 ounce;  
Essence of bergamot, 10 drops.

Should the pruritus be generalized the following ointment may be employed:

- ℞ Resorcin, 30 grains;  
Ichthyol, 1 drachm;  
Lanolin, 2 ounces.

#### GUAIACOL IN PYREXIA.

Before the Section on Medicine of the Royal Academy of Medicine in Ireland, held during November, 1896, and reported in the *British Medical Journal* of December 12, 1896, Dr. DRURY read a paper in which he drew attention to the uses and modes of the use of guaiacol, but selected the method of epidermic application recommended by Rondet in 1895, as a means of reducing temperature, as superior to either internal administration or by hypodermic injection. By this method one to ten minims were rubbed into the skin, previously washed, and the part covered with oiled silk. About fifty cases had been so treated. The conclusions arrived at were: (1) As a rule, no ill-effects follow its use. In one case of enteric fever in a female, after the use of ten minims on five successive evenings, collapse occurred several hours after the fifth application; the collapse was recovered from. (2) It very rarely fails to cause a fall of temperature, the fall being greater when the temperature is high than when it is only moderate in degree. (3) The fall reaches its maximum generally about one hour after administration, and is maintained for several hours. (4) After its use the skin becomes moist, and the patient generally sleeps. (5) It does not seem to

have any effect on the course of the disease which is the cause of the fever. (6) It seems to act on pyrexia, no matter what the disease may be which causes it. (7) It usually increases secretion of urine, diminishes the night sweats of phthisis, and often relieves the cough. (8) Cardiac failure appears to be the only contraindication to its use.

A series of cases were then given in illustration, most of which were used merely as test cases, the drug not being used as an ordinary line of treatment. Its routine use was not recommended; but for exceptional cases, where temperature is itself a danger, it is considered a safe as well as a simple and pretty certain method of reducing temperature.

Dr. CRAIG referred to charts of three enteric patients in which the drug had been used on occasions when the temperature became high; a marked fall followed in each case, and that without any injurious effects. It seemed to him that the drug acted by producing perspiration, and that it was the evaporation that caused the reduction of temperature.

Dr. JOHN W. MOORE said that if Dr. Craig's explanation of the action of the drug was correct they would not look forward with confidence to its effect as a reducer of hyperpyrexia in acute rheumatism. Dr. Moore would enter an emphatic protest against indiscriminate attempts to reduce temperature, especially in typhoid fever. The effects of guaiacol in pulmonary consumption were altogether different from its operation in other cases. Its effects when given internally in pulmonary consumption were not so immediate and extreme as when it was used epidermically, and rather depended upon its antiseptic properties and its power of reducing the septicemic conditions of that disease.

Dr. O'CARROLL said he had used guaiacol in phthisis and only hypodermically with the result of always reducing temperature, and without collapse. He preferred the hypodermic application, because they could measure the drug more accurately than in the case of the endermic method.

Dr. WALTER SMITH said the statement that a few minims of this drug rubbed into the skin could reduce temperature within an hour implied two things, namely, that the drug was absorbed, and that it produced a remarkable effect on the interior tissues of the body. He would confine his remarks to the pharmacology of guaiacol. The fact that it was capable of free administration in

the ways described proved that it was comparatively non-irritant; and yet it was closely related to the phenols and other members of the carbolic acid group. How then did it come about that, whilst they dare not rub the poisonous carbolic acid into the surface, they could do so with guaiacol, which was the chief representative of the creosote group, and find it comparatively harmless?

The PRESIDENT said the outcome of the discussion seemed to be that they had got a drug which was not only very useful but also very dangerous. He had reduced temperature with guaiacol in one or two cases with good effect. It had been said that the drug acted by producing perspiration; but it had also been stated that it was a powerful vasomotor constrictor. If that were so, its action might be mechanical. It was also an anesthetic, and had been used frequently for the relief of pleuritic and neuralgic pains. The hypodermic injection of guaiacol had been followed by most alarming collapse.

---

#### THE TREATMENT OF PUTRID BRONCHITIS.

*L'Abeille Médicale* of November 28, 1896, asserts that ROSENFELD has obtained good results in the treatment of putrid bronchitis by the injection of a five-per-cent. solution of nitrate of silver into the trachea. He asserts that one to two cubic centimeters of this solution may be injected each day without provoking an excessive cough. As a result there is a diminution in the quantity of the sputum, disappearance of its fetid odor, and an amelioration of the bronchial symptoms

---

#### THE TREATMENT OF ACUTE OTITIS MEDIA.

In the *Journal of the American Medical Association* of December 19, 1896, NORVAL PIERCE tells us that in this condition local bleeding has been carefully eschewed. The writer regards cataplasms as not only of doubtful service but actually harmful. They denude the skin of its protective coverings, and thus open up new portals for the entrance of infection. And if a mastoid operation should become necessary the dangers of sepsis are increased by the raw suppurating surface left by the blister in the very field of operating. Further, he is far from being convinced that they have any marked influence on the pain or course of the inflammation.

He regards the employment of cold as of distinct worth in many cases. This is employed by means of a Leiter's coil or a common ice-bag. The ordinary condom is a very good form of bag, being light and flexible, and on account of its peculiar shape especially adapted for coiling around the mastoid region. Heat may be employed, if deemed necessary, by applying hot antiseptic fomentations or the sand-bag.

Anodynes and all other drops have been abandoned. That anodynes are absorbed at all when dropped into the ear is doubtful; that they are infectious is certain. Therefore, as our whole endeavor is toward asepsis they have been abandoned. Narcotics for the relief of pain are best employed internally or hypodermically. Syringing has also been proscribed for reasons already mentioned in speaking of drops. Before perforation occurs irrigation can do no good as a means of cleansing and antiseptics in the middle ear, because the intact tympanic membrane closes off the cavity from the external auditory canal. The external auditory canal may be rendered aseptic much more readily by a moist dressing. It is the writer's experience that irrigation, as a means of applying heat or cold for their antiphlogistic or quieting effects, is not well borne—that is, in a number of cases it has added to the pain and increased the congestion. Besides, an apparatus which will enable us to use continuous irrigation in the external auditory canal is very cumbersome. Wetting the bed and the patient is almost unavoidable, especially when the patient is young. Intermittent hot irrigation has proven harmful in his hands. Occasionally syringing with sterilized saline solution has been allowed to clear the external auditory canal when the secretions take on a cheesy character which accumulates about the walls and membrane. In this connection Pierce exhibited a syringe which he had had made for him by McElroy. It is of glass, which may be rendered aseptic by boiling. In addition it has a removable nozzle. By this device the nozzle, which is the only part in danger of infection, may be changed after each time it is used. Another point in its favor is its extreme cheapness.

Politization is never performed in acute otitis media, either before or after perforation. He regards the procedure in these cases as dangerous, as by it fresh organisms are probably driven into the ear or into the mastoid antrum each time it is performed.

The blowing of the contents of the Eusta-

chian tube into the tympanic cavity is not only unreasonable, but in a high degree dangerous. The mucous purulent contents of the tube may drain off into the pharynx; indeed, the ciliary movements of the epithelium lining the tube renders this quite easy. Why, then, force the more or less septic mucus into the middle ear, whence it can escape only with the greatest difficulty? If our modern observations are correct, and we accept the dictum that the violence and chronicity of otitis is largely due to the amount of secondary infection, are we justified in supplying this very infection-bearing material by our Politization, in order to accomplish a passing re-establishment of ventilation of the middle ear? Surely not. The writer does not believe we are warranted in doing so, even after perforation has occurred. With a perforation it has been said that by Politization we aid in emptying not only the Eustachian tube, but also the middle ear, by driving the contents into the external auditory canal. The same objections are as valid here as they were in regard to Politization before perforation. We unnecessarily run the risk of forcing septic matter from the tube into the middle ear. As regards the discharge, that may be much more readily evacuated from the cavity by means of the capillarity of an aseptic, or better an antiseptic, gauze drain.

Politization is used, albeit with great care, after the discharge has ceased, the perforation closed and due attention paid to the condition of the nose and naso-pharynx. If an inflammation persists here after closure of a perforation, he substitutes Delstanché's rarefacteur, inasmuch as it accomplishes almost as much as Politization in preventing adhesions and ankylosis. If there are indications of a tendency toward adhesions before closure occurs, he employs tubal injections of vasenogen with external massage by means of the rarefacteur, or the latter procedure alone. If fever is present the patient is kept in a recumbent position when possible, although he has had a number of ambulatory patients with temperatures of 99° or 100° F. who made satisfactory recoveries. Obstipation is most usually relieved by the mild chloride of mercury, five to ten grains, combined with an equal quantity of bicarbonate of sodium. When he has seen the case soon enough he has never waited for spontaneous rupture of the drumhead.

Paracentesis has in the writer's hands given the most satisfactory results. Pierce

regards pain with or without fever, and the demonstrable presence of fluid in the middle ear, as positive indications for its performance in acute troubles. As negative indications: (1) the presence of fluid in the middle ear without pain or fever; (2) pain, continuing for twenty-four hours with congestion, but without fever or the demonstrable presence of fluid.

The strictest antiseptics should always be observed. If possible the auditory canal is packed with an ordinary dressing for as long a time as possible before the operation. This moist dressing will be the means of conducting the heat or cold of external applications to the deeper structures. If this is not advisable the canal is carefully swabbed out with sublimate, 1:1000, immediately before the operation. The point which Pierce regards with the greatest favor for incising the membrane is along its inferior circumference, a fraction of a millimeter from its margin.

The position for incision should be the most dependent part of the cavity, and give the greatest chance for the escape of the fluid contents. In skilled hands there is no danger of injuring the fenestra rotunda. With adults anesthesia is unnecessary; when necessary in children, ethyl bromide is used. After the paracentesis the discharge and blood is carefully swabbed away by means of sterilized cotton pledgets. These pledgets are kept constantly on hand and are prepared in the following manner: common toothpicks are used as carriers and the ends of them wrapped with absorbent cotton; test-tubes are filled with these, and the tubes stopped with cotton as is done in preparing them for bacteriological purposes; the whole is then sterilized by means of dry heat. In this way we have always at hand thoroughly sterilized swabs. The external auditory canal is then packed with a strip of sterilized gauze one-fourth to one-half inch broad, care being taken that it barely touches the membrane. As our view of the drumhead is shut off as soon as we introduce the end of the gauze into the auditory canal, he has devised a probe for packing the gauze. It is graduated in millimeters, and by taking the measure of the depth of the canal before introducing the gauze we can see at any time to what depth the gauze has been introduced. This probe is also roughened on the end so that it more readily catches the gauze. He has used iodoform, sublimate, and boracic gauze. Iodoform gauze is irritating to individuals and objectionable on account of its odor, but

on the whole it has been found the most satisfactory. The naphtholated chinolin gauze of Haug would seem to be specially suitable for this purpose, as pointed out by Fougerey. The gauze contains five per cent. chinolin and 2.5 per cent. naphthol. This combination forms a salt which is deodorant, is highly antiseptic, and is soluble in pathological fluids.

After the gauze is in place the vestibule of the auditory canal and the conchæ are packed with sterilized cotton; the whole is held in place by collodion applied from the edges of the cotton to the skin. It is very remarkable what an enormous amount of fluid may be extruded in some cases after such a dressing; frequently the dressing becomes saturated twice or thrice daily. In these cases it were better to put on a voluminous external dressing held in place by a bandage.

In fact, by paracentesis and the subsequent antiseptic dressings all the indications for the relief of acute otitis media are met. If there has existed a diminished atmospheric pressure paracentesis equalizes this as speedily as Politzerization. The congestion is reduced by the local hemorrhage necessarily accompanying the operation. Pain is more effectually relieved in this way in the majority of cases than in any other. The cavum is continuously emptied of its contents by the capillary attraction of the gauze drain, while additional germs are prevented from invading the cavity from the external auditory canal.

While the author is unable to give comparative statistics of this and other methods of treatment, he says that by this mode the course of all cases of acute otitis media is shortened, and the number of cases which go on to chronicity is greatly diminished. Surely complications such as those necessitating operations on the mastoid are very much reduced, and patients treated by this method are much less liable to recurrent attacks.

---

#### TREATMENT OF SCARLET FEVER BY BATHS.

According to *L'Abeille Médicale* of November 28, 1896, SCHILL, of Wiesbaden, has reported the results which he has obtained from the employment of baths at 95° and of ten minutes' duration, repeated twice a day during the first week of scarlet fever. He believes that the baths aid in relieving the fever and finally in producing free desquamation, and also believes that such a treatment distinctly decreases the danger of complications.

*THE TREATMENT OF CROUPOUS PNEUMONIA BY THE HYDROCHLORATE OF PILOCARPINE.*

BLIMONAY has employed the hydrochlorate of pilocarpine in sixteen cases of croupous pneumonia, varying in age from two to twenty-five years. The dose which he administered was  $1\frac{1}{2}$  grains in twenty-four hours. After this the dose was progressively diminished. The medicine was invariably given by the stomach rather than hypodermically, and dissolved in water. The patients also received one or two ounces of brandy. No other treatment either internal or external was employed. In nine of these cases the treatment was instituted on the third day of the disease; in the other cases on the fourth day. The conclusions which he arrives at are as follows: Pilocarpine administered on the third or fourth day of the illness exercises no abortive influence over the disease, the attack running on uninfluenced in its duration.

Pilocarpine is not markedly opposed to the spread of a pulmonary inflammation. After pilocarpine is given there is a rapid fall of temperature, which however is not permanent. The pneumonia usually terminates not by crisis but by a lysis or false crisis. Large doses of pilocarpine are of value only in young persons or those who are robust. Should symptoms of salivation come on the treatment must be suspended. In two cases when vomiting came on this symptom was controlled by morphine.—*Rev. de Thérap. Médico-Chirurgicale*, Dec. 1, 1896.

*SULPHONAL IN THE TREATMENT OF NIGHT SWEATS.*

COMBEMALE and DESCHEEMAKER are stated by *Revue de Thérapeutique Médico-Chirurgicale* of December 1, 1896, to have obtained excellent results from the use of sulphonal in the night sweats of phthisis. From fifteen to thirty grains of the drug are given each night. The cough is also diminished. In the very advanced stages of tuberculosis, however, the influence of this drug over the sweat is not marked.

*THE INDICATIONS, DANGERS, AND TECHNIQUE OF UTERINE CURETTAGE.*

In the *University Medical Magazine* for November, 1896, R. C. NORRIS contributes an exceedingly practical and useful article with

this title. He points out that when good judgment has been exercised in the selection of an appropriate case for uterine curettage, the next important step is that the physician should be absolutely certain of his knowledge of the dangers of that operation, and of the proper technique to be employed in order to escape those dangers. Many general practitioners will undertake to curette the uterus who would shrink from a vaginal hysterectomy or even a perineorrhaphy and trachelorrhaphy.

It is very unfortunate that the entering so important an organ as the uterus with various instruments is generally considered an operation of minor importance. It is not exaggeration to affirm that the proper selection and skilful execution of curettage of the uterus, especially when resorted to at a period remote from the puerperium, requires a greater degree of sound surgical judgment, a more intimate knowledge of surgical technique, and a larger share of surgical skill, than are necessary for the repair of a lacerated cervix or a torn perineum.

Briefly stated, the dangers to be avoided are: the introduction of infection which may be followed by serious inflammation of the tubes, the ovaries, and the peritoneum, and even by death from septicemia; laceration of the cervix or of the vaginal vaults, due to improperly executed dilatation; rupture of purulent collections in the pelvis, when these, through faulty diagnosis, have been overlooked; perforation of the uterine wall by the curette, the forceps, or other instruments; the induction of abortion through a mistake in diagnosis; the occurrence of serious hemorrhage; and, very rarely, the possibility of ultimate obliteration of the uterine cavity.

A proper selection of cases for uterine curettage and a knowledge of its technique will reduce these dangers to a minimum.

The time selected for operation in non-puerperal cases should be a few days after the cessation of a menstrual period, in order that sufficient time may be secured during which the endometrium will be regenerated. A preliminary urinalysis should be made. Twenty-four hours before the operation the patient should be put to bed; a saline purge having been administered the day before. The vulva and the vagina must be systematically cleansed the evening before, and the morning of the operation, in the following manner: Thorough scrubbing with green soap and water by means of pledgets of cotton fastened to a sponge-holder should be

followed by free irrigation with a 1-to-1000 bichloride solution, after which the vagina is loosely packed with bichloride or iodoform gauze. Before the patient is anesthetized the rectum should be emptied by one or more enémata, and the urine should be drawn. The instruments he has found most useful for curetting the puerperal and the non-puerperal uterus were then shown. They should always be sterilized in boiling water for fifteen minutes before the patient is anesthetized.

The operator and those assisting him should cleanse their hands with the same care as for a hysterectomy, using an abundance of hot water, with soap and nail-brush, followed by scrubbing with alcohol for five minutes, and a final immersion in a 1-to-1000 bichloride solution.

The patient (anesthetized) is placed in the lithotomy position on a table, when it is always desirable to make a bimanual examination of the pelvic organs to be sure that serious lesions have not been overlooked. Final cleansing as above described is then made, the anterior lip of the cervix is grasped with a double tenaculum and is gently drawn into view when not fixed by inflammatory products, and the cervical canal is thoroughly cleansed. Sometimes it is desirable to retract the perineum. A self-retaining speculum, such as Edebohl's, is very useful for that purpose, especially when one has few or no assistants.

Dilatation of the cervix is not usually required for puerperal cases, but is always employed for the non-puerperal uterus in order to obtain free drainage, which is an essential feature of the operation. For that purpose the anterior lip of the cervix is grasped and steadied with the double tenaculum, and the smaller dilator is introduced. The writer prefers the branched dilators to the graduated bougies; and to avoid lacerating the cervix or even tearing through the posterior wall of the cervix into the peritoneal cavity, care should be taken to learn the direction of the uterine canal, to open the cervix gradually with the smaller instrument, and to be sure the larger instrument passes the internal os before forcible dilatation is begun. After dilating laterally, say for a half-inch, the tension of the instrument is relieved and dilatation to the same extent in antero-posterior and oblique directions is practiced, the position of the blades of the instrument being turned at intervals so as to effect dilatation equally in all directions. In

multiparæ sufficient dilatation can usually be made with safety to admit the finger into the uterine cavity; in nulliparæ an inch registered on the scale of the dilator is sufficient. Usually fifteen minutes should be consumed to complete the dilatation, although the time will depend upon the softness or rigidity of the tissues. A finger placed behind the cervix will indicate the degree of tension to which the tissues are being subjected. The uterine cavity should now be thoroughly flushed with a 1-to-2000 bichloride solution passed through a two-way male catheter or a uterine double-nozzle having a return flow. This plan is preferable to the douche-curette, an instrument frequently employed but not readily kept clean. The sharp curette is next passed to the fundus, and with one hand supporting the uterus through the abdominal wall, the entire cavity is systematically scraped until the cutting edge of the curette imparts a scratching or gritty sensation, which announces the fact that the endometrium has been passed and that the muscle wall of the uterus has been reached. Our work must be thorough, and the entire endometrium must be removed if possible. Areas of diseased and infected endometrium untouched by the curette only serve to re-create and perpetuate the disease our treatment aims wholly to destroy. The regeneration of the mucosa begins in the depths of the utricular glands embedded in the uterine muscle, and our effort is to completely destroy the diseased membrane in order that a new one may be formed. Particular attention, therefore, must be paid to the fundus and to the uterine cornua. For these regions Simon's spoon and Sims's angular curette are especially useful. For the lateral walls of the uterus Sims's sharp curette is preferred. While one instrument may be sufficient, the author has been better satisfied to use three, because the angle of the cutting edge in each is best adapted to a different plane of the surfaces to be scraped. The uterus should again be douched, and the débris removed with the curette forceps—an instrument to be employed with caution, since many of the reported cases of uterine perforation have occurred with it.

When the womb has been emptied of all débris and has been douched, the cavity is swabbed with iodized phenol or a fifty-percent. solution of carbolic acid in glycerin. A pledget of cotton placed around the cervix and the stream from the douche will protect the vaginal and vulvar mucous membrane during the cauterization of the endometrium.

Finally, a strip of iodoform or acetanilid gauze, one inch wide and one yard long, squeezed out of the bichloride solution, is packed into the uterus, either through a cervical speculum or preferably with a slender uterine dressing forceps. If the uterus is large and subinvolved and uterine contractions are desired to promote involution, or if the bleeding is very free, the gauze packing is firmly placed; if only drainage is desired, the packing is more loosely applied. The end of the gauze protrudes into the vagina, which is filled with a loose tampon of gauze. An occlusive dressing is placed over the vulva.

If necessary, the urine is drawn in eight or twelve hours. The vaginal packing is removed at the end of forty-eight hours, the vagina douched, and the gauze renewed. The gauze in the uterus is removed on the third or fourth day, daily vaginal douches of bichloride solution, 1-to-4000, being employed until and immediately after the uterine packing is removed. It is desirable to have the patient rest in bed for a week and at the next menstrual period, during which the flow is likely to be scanty. In septic cases after abortion or labor the uterine and vaginal packing should be removed at the end of twenty-four hours, and the vagina and uterus should be freely irrigated, after which the gauze may be renewed.

The douche nozzle used for puerperal cases should have a large calibre, as this freely flushes the cavity. The mechanical advantage of a copious stream to remove débris from the uterus is self-evident. The curette also should be proportionately large.

The writer states that his remarks on this subject contain nothing new. It has been his purpose to make them practical, and to emphasize the fact that through timely interference with the uterine curette, along the lines he has tried to indicate, the lives of a few of our patients will be spared, some of them will escape the removal of their pelvic organs, and many of them will avoid a life of discomfort resulting from the milder grades of pelvic inflammatory disease.

He alludes to the fact that many gynecologists would criticize the wisdom of an attempt to stimulate the employment of the uterine curette by men who from choice or environment are general practitioners. There is no reason why you should not use an instrument potent for good as well as for evil, provided you will use it with intelligence and with a knowledge of its dangers and its limitations.

#### HINTS ON SEA-VOYAGES FOR PATIENTS.

While the majority of readers of the *GAZETTE* will not have patients who are benefited by sea-voyages, the following suggestions offered by BARBER in the *British Medical Journal* of December 19, 1896, will be of interest to a few. Barber tells us that while serving at sea he was struck by the number of people sent away for the benefit of their health with absolutely no directions as to the precautions that should be observed in the tropics, and as to matters which greatly conduce to the comfort and well-being of the patient.

In the first place, it is well that an entire stateroom should be secured, especially for phthisical patients, as they are at once a source of infection and also a great annoyance to those occupying the same cabin, and should their complaint become serious it is a necessity.

A crowded ship should be avoided, as unless the patient has an attendant he or she cannot have the attention from the stewards and stewardesses that a severe case demands. These last make most excellent nurses, but naturally they are extremely busy in a crowded ship. The stateroom selected should be amidships, where the motion and vibration are least felt, and for a voyage via the Suez Canal should be on the starboard side homeward bound and the port side outward bound.

The patient should be told not to neglect to wear a cummerbund over his pajamas (not night-dress), as the neglect of this precaution frequently leads to severe abdominal pain and diarrhea, and often colitis, owing to the free perspiration which occurs in the tropics being suddenly checked by a stream of cold air from an open port, hatchway, or punkah. This, of course, greatly militates against the good done by a trip.

The patient should never sleep on deck, especially if suffering from a throat disorder, and he should be told to wear a solar topee as soon as he arrives in the tropics, which protects the neck, as those in indifferent health are particularly liable to sunstroke, sun-headache, and thermic fever. I have recently had a patient under my care who was sent away for the benefit of her lungs, which it was feared might become tuberculous. In Cairo she suffered from sunstroke, and two months later came under my care at Colombo suffering from thermic fever and hill-diarrhea contracted up country, all of which might have been avoided with ordinary care. The patient should be told to keep on deck as

much as possible, and not to stay below as they so often do; but they should not sit under a single awning which allows the sun's rays to penetrate. Clothing should be suited to the varying climates—warm clothes for the Atlantic and Mediterranean (according to the time of year) and flannel for the tropics.

The writer thinks all alcoholic cases should be put under the charge of the ship's surgeon at the commencement of the voyage, as he is able to see that they get no liquor. The morning bath should be taken warm by malarial cases, and those who are in delicate health, especially those suffering from enlarged spleen. Very strict orders should be given about diet, as passengers generally eat too much and take too little exercise in spite of the best advice. In the P. and O. service any diet can be procured on the recommendation of the ship's surgeon.

A good deal has been written about seasickness lately. The writer has found the following prescription of great value:

℞ Chloroform, 1 minim;  
Tincture nux vomica, 1 minim;  
Tincture lavender, 10 minims;  
Water, ad 1 drachm.

Mix.

This should be well shaken, and one teaspoonful taken every hour until the nausea is relieved, and five minims acetate of morphine, liquid, if there is much pain. A tight binder will often relieve the pain due to straining, especially in uterine cases. Alcohol is unnecessary in most cases, and the writer thinks many people take too much if left to themselves. Milk and soda, beef-tea and beef-jelly should be given in small quantities at frequent intervals, and crushed ice given to suck.

He thinks many patients would derive considerably more benefit from the voyage if medical men made it a rule to give them a few hints before sending them on board ship; and also not to neglect to give them a letter describing their cases, which they may hand to the ship's surgeon should they find it necessary to consult him.

#### A POWDER FOR ULCER OF THE LEG.

Finely powdered chloride of sodium, 10 drachms;  
Powdered menthol, 1 drachm.

Mix thoroughly and use as a dusting powder after thoroughly washing the surface of the ulcer clean.

This is particularly useful in atonic slow ulcers of the leg, and aids very materially in maintaining antiseptics and producing healing.—*Journal de Médecine de Paris*, 1896.

#### SULPHATE OF SODA AS A HEMOSTATIC.

The *Journal de Médecine de Paris* of November 29, 1896, records the fact that sulphate of sodium is useful when administered internally in oozing hemorrhage as was originally pointed out by Kussmaal. Recently Reverdin has employed with success small doses of sulphate of sodium, amounting to  $1\frac{1}{2}$  grains every hour, in the treatment of grave capillary hemorrhages, whether they be spontaneous or traumatic in origin. Thus in one case in particular in which consecutive hemorrhage followed extirpation of a small benign subcutaneous tumor, and where the bleeding lasted for a very long period of time, arrest of the hemorrhage followed upon the administration of this drug. He has also found it of value in menorrhagia.

Reverdin noted, however, the curious fact that while the sulphate of sodium when injected into the blood or given by the stomach produces these effects, its use hypodermically was without result.

#### CHRONIC SULPHONAL POISONING.

SCHULZ (*Neurologisches Centralblatt*, October, 1896) records a case of chronic sulphonational poisoning with fatal ending. The patient, a woman aged fifty-nine, had been under treatment some years for headaches, constipation, and restlessness, and was extremely hysterical. On account of sleeplessness she had recently been taking sulphonational in doses of fifteen grains, and had taken altogether about half an ounce within a month. When admitted to hospital for obstinate constipation with vomiting, there was a smell of acetone in the breath, the tongue was dry and furred, and there was great thirst, with restlessness and insomnia. All the organs otherwise were normal; the urine was normal. The next evening twenty-five grains of sulphonational was given, and the following day the urine was scanty, brownish-red in color, but free from albumen. Four days later the gait was unsteady, and five days after this there was weakness of the limbs and anesthesia of the legs down to the ankles; knee-jerks, previously normal, were now difficult to obtain. Weakness increased, the knee-jerks disappeared, incontinence of urine and feces occurred, and two days later the patient died suddenly. Since the single dose of sulphonational mentioned the urine had continued brownish-red with no albumen, but a few altered red-blood corpuscles. The color was found to be due to hematomporphyrin. Schulz considers that the

toxic results after the one dose of sulphonal were due to the obstinate constipation present causing the sulphonal to be retained in the body longer than usual. Great caution should therefore be exercised in ordering sulphonal for patients who are constipated, and where it is ordered a careful watch should be kept on the urine for hemato-porphyrin.—*British Medical Journal*, Nov. 28, 1896.

#### CHEMICAL TREATMENT OF MORPHINISM.

ERLENMEYER (*Le Progrès Médical*, Aug. 1, 1896) has for three years abandoned the method of rapidly cutting off morphine, which is associated with his name, in favor of one which he finds superior in respect of results. He noticed that the sudden deprivation of a morphinomaniac's drug was associated with the symptoms, both direct and remote, of hyperacid dyspepsia; actual investigation showed that when the sufferings caused by its discontinuance were most severe the sound revealed the presence of excess of hydrochloric acid in the stomach. The reason of this can be deduced from Alt's researches, which show that morphine injected under the skin is largely excreted into the stomach, where it must exert a narcotic influence both upon the gastric glands, inhibiting their secretion, and upon the nerves, benumbing their sensibility. When the source of these actions is removed exactly the reverse changes take place: an excess of acid is poured forth upon the hypersensitive nerve-endings, producing the symptoms of gastric disorder and of reflex nervous disturbances. To counteract this effect Hitzig washed out the stomach and introduced an alkaline solution of Carlsbad salts in place of the strongly acid gastric juice, with marked relief. Erlenmeyer aims, on the other hand, at the neutralization of the hydrochloric acid *in situ* by means of Fachingen water, which contains 0.35 per cent. of bicarbonate of soda. He has treated over thirty cases in this manner, with an entire absence of either gastric or nervous symptoms. It is noteworthy that, although the patients are perfectly well and comfortable without it, the craving for morphine remains unappeased, and they still shriek like maniacs for the drug. To make his treatment absolutely systematic the author intends to administer hydrochloric acid during the morphine-taking period, so as to avoid the subacidity of the stomach, and to retain the natural relations of the nerves to the acid.—*British Medical Journal*, Nov. 28, 1896.

#### ATROPINE AS A MEANS OF MITIGATING CERTAIN INCONVENIENCES OF QUININE.

In the *Lyon Medical* of January 3 there is an article on this subject by P. AUBERT, who calls attention to a new employment of atropine in the correction of several inconveniences caused by quinine.

Among the symptoms which are produced by the administration of quinine, even in doses of from six to eight grains, the most frequent are buzzing and ringing in the ears, a sound like that of rushing water, deafness, vertigo, and headache. In certain cases these symptoms are accentuated, and the patients refuse to continue the use of the drug.

M. Aubert relates the histories of three cases of neuralgia in which he was able to attenuate to a very great degree, and even to suppress, these disagreeable symptoms by the addition of small doses of atropine sulphate. From five to seven grains of quinine were given at a time, and to each dose the author added 0.007 of a grain of atropine sulphate. In one case this prevented the disagreeable symptoms, and in the two others greatly moderated them. The periodical pains were allayed, and no appreciable symptom of atropinism was experienced.

M. Aubert states that he has not had occasion to use larger doses of quinine, and does not know what the results would be with larger quantities. These facts, however, seem to be worthy of being called to the attention of physicians, as he is not aware that atropine has before been employed for the purpose of mitigating the disagreeable symptoms provoked by quinine.—*New York Medical Journal*, Jan. 23, 1897.

#### SHOULD THE INTERNAL USE OF ATROPINE BE DISCONTINUED?

LEPINE (*La Semaine Médicale*, Nov. 25, 1896) calls attention to the fact that more deaths have followed medicinal doses of atropine than of any other drug. If possible, therefore, other drugs should be substituted for it. Atropine has been used in the following diseases: (1) Neuralgia and other painful affections. Considering the large number of analgesics available it should be used in the present day in exceptional cases only—for example, in angina pectoris. (2) Whooping-cough and asthma. If the cases are severe and have resisted all other treatment, atropine may be tried. The same applies to (3)

epilepsy. (4) It is very doubtful whether it is of any use in hysteria, paralysis agitans, and other tremors. (5) Chronic constipation. As there are plenty of substitutes its use should be discontinued. (6) Lead colic. In this the subcutaneous use of atropine has more disadvantages than advantages. (7) Nocturnal enuresis. Great caution is necessary, since large doses are required as a rule. (8) As a cardiac tonic, and in those cases of permanent bradycardia which often end in epilepsy. Atropine has been tried without much success in the latter cases, possibly because a slow pulse does not always correspond to a slowly acting heart. According to Dehio it may benefit slight cases of cardiac irregularity, but is without effect in severe. (9) In night sweats it acts well, but although small doses tend to prevent collapse, which is common in phthisical patients, larger ones increase the liability to it. To begin with a dose of  $\frac{1}{100}$  grain is unjustifiable in advanced cases of phthisis. (10) In chronic hypersecretion of HCl by the gastric mucosa several observers have found that atropine diminished the secretion, but others deny this. However, considering the bad effects of this hypersecretion on the gastric mucosa, in the present state of our knowledge atropine must still be tried. (11) Some observers state that atropine given hypodermically arrests hemorrhage (hemoptysis, etc.) by its action on the arterioles. (12) The injection of atropine before the administration of chloroform to prevent syncope has been given up by surgeons. (13) It has been recommended as an antidote to barium salts, hydrocyanic acid, nicotine, pilocarpine, veratrine and muscarin poisoning. (14) The question of its use as an antidote to opium is left by the author for a further communication.—*British Medical Journal*, Jan. 9, 1897.

---

**TREATMENT OF A CASE OF ADULT HYDROCEPHALUS BY SUPRATENTORIAL AND SUBTENTORIAL OPERATIONS.**

WILLIAM GORDON in *The Lancet* for January 9, 1897, discussed the above subject. He says when we recommend trephining for the relief of intracranial pressure it cannot be a matter of indifference whether the opening be above or below the tentorium, even when we do not aim at the removal of the cause. When the cause is situated below the tentorium this is especially obvious because the subtentorial space is so small compared

to the general cranial cavity, its walls and roof are so unyielding, its outlet above and below so narrow, and a portion of its contents so vitally important and so sensitive to compression.

Adult internal hydrocephalus, apart from acute meningitis, is almost always due to subtentorial tumor, and is indeed a very common consequence of such a tumor. The tumor causes the hydrocephalus either (a) by compressing the veins of Galen; (b) compressing the outlet from the lateral ventricles; or (c) compressing both. There is a certain number of cases where, at the necropsy, the mechanism has seemed uncertain, but one of the above appears in most instances to be the correct explanation. From this it follows that in order permanently to remove the hydrocephalus in a case of tumor (at all events, in most instances) the tumor must (1) be removed; (2) subside—"be absorbed;" or (3) become arrested at the same time that relief is afforded by some means to the compression already set up before arrest occurred.

As to removal, in the first case the opening would naturally be made below the tentorium. But such cases are few, because at present there are few subtentorial tumors which admit of removal. Some are undiscoverable from lack of exact localizing data, and cerebellar tumors are very apt to belong to this class; some are inaccessible on account of their remoteness from the trephine hole; some are untouchable because either of their position amongst vital structures, their extent, their nature, their attachments, or their complications. The statistics show this. Dr. Hale White's series of 100 brain tumors includes 41 in which there was a subtentorial growth, 6 in the pons, 1 in the pons and medulla, 1 in the medulla, and 4 growing from the dura mater. Of these 41, White considered that 6 cerebellar tumors and 1 growing from the dura mater could probably have been removed—that is, about 17.5 per cent., a percentage which seems to contrast very favorably with his estimate for the whole brain, viz., 10, or at most 14, per cent. There is, however, a further consideration on which Dr. White lays emphasis: How many of these were discoverable? Cerebellar growths, which form the majority of those removable, are apt to be latent or to give little more than so-called "general symptoms"—e.g., headache, vomiting, and optic neuritis. But the optic neuritis in cerebellar cases is remarkably constant, more so, perhaps, than in tumors of any other part of the brain, usually

early and often obtrusive, because loss of sight is often an early event. If, therefore, optic neuritis were absent he cannot but think that we should hesitate to trephine for the removal of a supposed cerebellar growth unless we had other very pronounced evidences of its existence.

We may secure the subsidence of the tumor. Whether this ever applies to any tumor except a gumma is doubtful, but in any case subsidence requires time, and when symptoms are severe time cannot be afforded. Sudden death may intervene and is far from uncommon. It is, indeed, rather startling to note that out of seven cases which Dr. Hale White considered removable three died suddenly. Sight may be lost while we are waiting, and the combination of optic neuritis due to tumor and compression of the chiasma due to hydrocephalus is apt sometimes to act rapidly. Lastly, it is conceivable that the cortex may suffer from long-continued pressure. What can we do in the meantime? Two operations are open to us: we may trephine above the tentorium and tap or even drain the lateral ventricles (bearing in mind the two main risks of sepsis and over-quick escape of fluid), or we may trephine below the tentorium and allow the subarachnoid space to empty itself. All we want is temporary relief, and either may afford it.

As to arrest, but few cerebellar tumors are syphilitic, and cerebellar tumors form the majority of subtentorial tumors, therefore presumably this majority will not subside under iodide and mercury or otherwise. We can then only hope for arrest, and fortunately arrest is not very rare, especially in the case of tuberculous masses. But we must manage more than a mere arrest of the growth, for there is pressure already set up and we have to relieve it, and relieve it permanently. For this purpose a supratentorial opening will not do, since tapping the lateral ventricles is plainly out of place; and permanent drainage is too dangerous to be thought of. But another possibility presents itself. May not an opening made below the tentorium effect what we require? It will certainly relieve the general subtentorial pressure, and even when skin and muscle are closed over it, it will continue to give additional space. By thus relieving the general pressure may we not fairly expect it also to relieve the local pressure on the veins of Galen or the outlet from the lateral ventricles? If so, the cause of the hydrocephalus should disappear and the hydrocephalus with it. In the following

case the conclusion that something of this sort has occurred can scarcely be escaped:

The patient, a rather strumous-looking girl aged seventeen years, was admitted to the Devon and Exeter Hospital on December 28, 1894, with complete blindness, well marked double optic neuritis, headache, and a history of vomiting. She was not anemic, had no symptoms of plumbism, and her urine was normal. She gave the following history, which her mother confirmed: Up to the preceding March she had been perfectly well, but about that time she noticed that when out walking in the dusk a dark shadow would suddenly come over her sight, and "for one or two minutes" she could not see. At first this was very occasional, but gradually it became more frequent, occurring several times in the same evening, and the loss of sight became longer, "three or four minutes at a time." Later this began to occur in the daytime as well, and soon looking at any bright light would take away her sight for several minutes. In the intervals vision was becoming progressively worse. She had always been subject to "bilious attacks" of headache and vomiting, but since March these had become more frequent—about once in two weeks, usually in the morning, and accompanied by vertigo. On November 5, 1894, she went to the West of England Eye Infirmary, being then almost blind. Pronounced double optic neuritis was found and the following note was made: "Vision of the right eye, shadows; of the left, 1-60. She has had for the past week shaking attacks down the right side, occasionally only the arm being affected. These attacks came on on alternate days, and she was sick the whole day. The attacks did not begin in any particular spot, and she did not lose consciousness. There is constant headache, most acute over the left ear; no tenderness of head discoverable, no paralysis of motion or sensation."

She was put on a mixture of bromide and iodide of potash, and for a time the headache and sickness disappeared, nor were there any more "shaking" attacks. On Christmas night she was awakened by intense headache all over her head, with violent vomiting and "shaking" all over, and great tenderness of the skull. She was admitted to the Devon and Exeter Hospital on the 28th. As regards past illnesses, she had had none lately; she had scarlet fever as a child, but it left no sequelæ. She had never had a blow on the head or any discharge

from, or pain in, either ear, and had never been deaf. Her father and mother were both alive and well, aged forty-six and forty-four years respectively. A brother and sister died in infancy from convulsions. Her mother's sister died from what appears to have been phthisis. There was no evidence of syphilis. The patient was a fairly nourished but somewhat drowsy looking girl. She was absolutely blind; speech clear but deliberate; her answers were intelligent but delayed, and then commencing rather suddenly in an unnecessarily loud tone. Memory was good. She walked easily and well when guided. There was a slight headache on the left side of the head between the ear and the occiput; there was no sickness and no giddiness, and the patient slept and ate well. She was given thirty grains of iodide three times a day with small doses of mercury. There was a very slight tremor of the right arm, which movement did not increase. No paralysis of motion or sensation was present. The right knee-jerk was greatly diminished, the left being normal. The condition of the cranial nerve was as follows: There was complete bilateral anosmia. Absolute blindness existed for the last week; the pupils were equal, but sluggish in reacting to light. No strabismus or nystagmus was present, but both lateral conjugate movements of the eyes seemed feeble. The heart, lungs and abdomen were natural, and the temperature was normal. The optic neuritis was very intense, and the swollen papillæ were rather pale. The diagnosis was intracranial tumor. The early blindness, occipital headache, early and sometimes severe vomiting and vertigo, with absence of motor or sensory paralysis, favored the suggestion that it was cerebellar. The "shaking attacks" in the arm and the persistent slight tremor in it, taken with the sluggish ocular movements, might have raised a suspicion of its being pontine, but pressure on the pons from above might, it was thought, explain these. The drowsiness, slow speech, and delayed answers, with the early blindness, were regarded as suggesting distention of the lateral ventricles. Putting everything together it was considered that the tumor was certainly subtentorial, and probably in the fore and under part of the cerebellum. As iodide and mercury were evidently useless, and it was possible that operation might in some measure restore the sight and relieve the headache, it was decided to trephine. It did not then occur to the author that trephining could prove to be more than a palliative

measure, and therefore the position of the opening seemed immaterial.

Accordingly, on January 1, 1895, the patient was trephined. The centre of an inch trephine was placed on a line drawn vertically from the external auditory meatus and three inches from the antero-posterior midline of the skull. The dura mater bulged and little, if any, pulsation could be perceived, and on incising it the brain bulged out so forcibly that to prevent an immediate and considerable hernia it was necessary to push a small trocar and cannula into the ventricle. About six drachms of clear, slightly albuminous fluid was drawn off. The brain bulged less and pulsation could be seen in it. The flaps were replaced and sutured. The patient rallied well and the wound did admirably. On the 3d some slight amnesia was noticed, and this was more marked next day, when some slight weakness was observed in the right side of the mouth and the right side of the tongue. These symptoms were considered to be due to the position of the opening, and soon disappeared, so that on the 7th they were noted to be gone. The temperature had remained normal since the operation, and the headache had completely left her; there was also no further vomiting or vertigo. The sight, however, had not returned and did not do so subsequently. Other symptoms now began to make their appearance: the speech became blurred and sibilant as if she were speaking with her mouth full of saliva; slight divergent squint was observed, apparently from weakness of the internal recti, and there was some nystagmus on looking towards the right. On the 8th there was slight proptosis, more marked on the right side, and slight nystagmus on looking either right or left; she was drowsy, with a furred tongue and offensive breath. There was defective sensation to touch over the lower part of the face on the right side, complete loss of sense of touch all over the right arm (the sense of pain was retained), and allochiria over the left arm; on the legs and trunk there was patchy anesthesia; the right leg felt "sleepy and tingling." On the 9th some weakness was noticed in the right hand, and the next day it became absolutely palsied; both knee-jerks were completely lost; there was no weakness of either leg. On the 11th the hand began to recover power, but there was slight ptosis noted on the left side. On the 14th, although there was no weakness of legs, she could not stand on attempting to do so (for the first time since the operation),

as there was marked incoordination, the legs being thrown wildly about. On the 17th the left pupil was noticed to be larger than the right, the right reacted slightly to light, but the left not at all. The relative size of the pupils after this date was somewhat variable, but when unequal the left was always the larger. On the 20th the hernia cerebri, which had been steadily increasing, had become so large that it was feared the skin over it might give way, and therefore an exploring needle was pushed through it into the ventricle and eleven drachms of fluid drawn off. On the 26th the patient was very drowsy and said her right leg felt sleeping and tingling again. Next day she complained of severe pain in the right side of the abdomen, which was extremely hyperesthetic. Her temperature rose to 103.2° F. with a slight rigor, and the right arm and leg became flaccid and powerless. With this the right knee-jerk, which like the left had been completely abolished, returned and became excessive, with ankle clonus, the left knee-jerk remaining absent. On the 30th she was very irritable and lay curled up on her right side. There was some occasional retraction of both sides of the mouth. On February 3 she was almost unconscious, scarcely recognized her mother's voice, and passed her motions under her. The temperature had again become normal. From this date she improved, the hyperesthesia and irritability passing off, and some return of power showing itself in the arm and leg; but the hernia was again increasing, and drowsiness became very marked. At last, on February 12, this almost amounted to unconsciousness; she evinced no interest in her surroundings and seemed steadily passing into coma. So serious did her condition appear that it was thought admissible to run the risk of draining the ventricle, and a small hydrocele trocar and cannula were again passed in through the hernia. Before withdrawing the cannula a very small (No. 1) catheter was pushed in and afterwards tied in place, large dressings being applied over it. A great quantity of fluid drained away, the catheter being kept in for three days. The effect of this drainage was unmistakable: improvement at once set in, and on February 18 a note was made that "she is much better, lies straight in bed, and is bright and cheerful." Her movements became brisk again and the drowsiness vanished. After the catheter was removed the drainage did not cease, but merely lessened, the fluid continuing to escape apparently along the track the

catheter had left. On February 25 the "hernia less tense, greatly better." The drainage now ceased, and with its cessation drowsiness began to return, so that on February 28 "she is very drowsy again; no drainage." On March 1 free drainage through the hernia recommenced spontaneously and went on intermittently for a fortnight, one or two days at a time with intervals of two or three days. With this the drowsiness again disappeared and remained absent, and she began to regain the flesh which she had lost. On March 11 it was noted that there was some weakness of the conjugate lateral movement of both eyes toward the right. Then came a week during which there was no drainage, and drowsiness again became very marked. It now occurred to the writer that a subtentorial opening might have the effect referred to above, and accordingly on March 21 a second operation was performed.

After raising the soft parts a three-quarter inch trephine-hole was made over the left cerebellar hemisphere, which bulged considerably. It was thought possible that the tumor might be cystic, and so a small trocar was passed in two directions forwards, inwards and upwards, but no fluid was found. The flap was replaced and sutured; the patient rallied well, and the wound did excellently. There has never been the slightest return of drowsiness since this second operation. An attack of vomiting and headache occurred about four months ago, which rapidly subsided under iodide and mercury.

On December 14 the reporter saw the girl at her home. She was perfectly intelligent, cheerful, and happy; she showed no trace of drowsiness, her answers were not delayed, and she only occasionally hesitated for a word. There had been no return of drainage through the hernia, and the hernia was greatly reduced in size and quite flaccid. This reduction was no doubt largely owing to a gentle continuous pressure applied by the operator. There was a considerable but soft bulging over the subtentorial trephine-hole. Smell was absent, but taste was present (said to be variable); sight remained absent and the discs were white and filled in, but without much change in the calibre of the vessels. The conjugate movement of both eyes was to the left (it used to be to the right), was weak, and there was some nystagmus in all directions. The pupils were large and equal, reacting slightly to light. There was no proptosis. Sensation to touch was normal on the face. There was very slight weakness

of the right side of the mouth, and the tongue deviated slightly to the right. Her right hand was powerless, but she could move the arm fairly. Both legs were very weak and she could not stand, but there did not seem to be much difference between them except that flexion of the ankle was weaker on the right than on the left; sensation was lost on the right leg from the foot to slightly above the knee, and on the right hand and half-way up the forearm. The plantar reflexes were normal, the left knee-jerk was lost, and the right exaggerated, and there was ankle clonus on the right side. The sphincters were normal. She had no pain of any kind and no sickness, had an abnormally good appetite, and had decidedly gained flesh. The growth seemed to have been arrested. Whether the arrest is permanent remains to be seen. If it was tuberculous, as the writer is inclined to think, tubercle might show itself sooner or later in the lungs. She had an occasional slight dry cough, but no physical signs in the chest.

The case was clearly one of intracranial tumor; it was also clearly one of subtentorial tumor; internal hydrocephalus was marked and increasing; a supratentorial trephining was a means of gaining time; and a subtentorial trephining appeared to remove the hydrocephalus permanently.

#### INTUSSUSCEPTION IN CHILDREN.

Mr. PICKERING PICK in the *Quarterly Medical Journal* for January, 1897, presents a valuable paper on Intussusception in Children. First of all, he advises distending the bowel by inflation of air, which he believes is a better and safer method of reducing the invagination by mechanical means than the distention of the bowel by water.

The manner of performing the inflation is as follows: The child should be clothed in a jacket of wool, and the legs and arms covered with wool and bandaged, as it is very important to keep it warm during the necessary manipulations. It is then anesthetized, and an ordinary enema pipe introduced into the rectum. This pipe is connected by means of a piece of india-rubber tubing to a pair of common bellows, or, if it is at hand, a Lund's inflator. The outside of the tube around the anus is carefully packed with wool, which is held in position by an assistant, so as to prevent the escape of air by the side of the tube. The child is now inverted and held by a nurse, whilst the bellows are slowly and steadily worked by an assistant. The sur-

geon should have his hand placed on the abdomen of the child so that he can feel the tumor. As the intestine is inflated he will gradually feel the colon becoming distended, and he can regulate the amount of air introduced and stop it as soon as he feels the colon is distended as far as is safe. If the plan succeeds and the invagination is reduced he will suddenly feel the tumor disappear from under his hand, and the air will become diffused over the whole abdomen, so that what was at first distention of the colon is now a uniform distention of the abdomen. He attaches more importance to this sign than to the sudden disappearance of the tumor as an indication that the intussusception has been reduced, because this latter sign is very liable to mislead. It frequently happens on inflating the intestine that the air causes a change in the position of the tumor, and it disappears from under the hand without the invagination being reduced, and if reliance be laid on this sign it may be thought that the intussusception has been relieved when this is not really so. The writer has more than once been deceived by this, and therefore he always looks out for the sudden diffusion of the air over the whole abdomen as the characteristic sign of reduction. If this is felt the child should be laid down and put quietly to bed, with as little movement as possible.

The author then passes on to a consideration of the treatment by the introduction of a fluid into the bowel; and in doing this great care must be taken, as serious injury to the bowel has been known to result from this proceeding.

The operation as regards its preliminaries is exactly the same as for the inflation of air. The child is swathed in wool, anesthetized, and inverted; a catheter connected by an india-rubber tube to a reservoir containing a pint and a half of the saline solution is introduced into the rectum, and being packed round with wool, is held by an assistant. The reservoir is now raised to the height of three feet above the anus and the fluid will be felt gradually distending the colon. It should be retained there for a few minutes, and then allowed to escape. An examination of the abdomen should now be made, and if the tumor has disappeared the infant should be returned to its bed and kept warm. No opiate should be given, as this may quiet the child and mask the symptoms, which otherwise would persist if a successful reduction has not been accomplished. Probably,

if the injection does not succeed in accomplishing its object the first time it is used it is wiser and safer not to resort to a second attempt, but to proceed to other measures. Some surgeons, however, recommend a second and a third trial.

A third method of reducing an intussusception other than by operation is as follows (this plan is not often successful, however, and can only be applied under certain conditions; that is to say, when the child's abdominal parietes are thin and there is no distention of the gut, so that the tumor can be very easily felt and almost grasped with the fingers): Place the child thoroughly under the influence of an anesthetic, so that the abdominal muscles are completely relaxed, then seize the gut between the forefinger and thumb immediately below the tumor and by a kneading movement gradually push the tumor backwards along the course of the colon. In this way he has succeeded in reducing an intussusception; but of course it is only applicable to the ileo-cæcal or ileo-colic varieties, and would be scarcely likely to succeed in a case of enteric intussusception. Ordinary massage has also been applied to the abdomen in the course of the colon, but the writer has never succeeded in reducing an intussusception in this way, though he has frequently tried it.

Treatment by operation is a very severe proceeding in infants and quite young children, and is often followed by death. There is a very strong feeling amongst some medical men that abdominal section on an infant under the age of twelve months is almost certainly fatal. But this is not so. Scattered up and down the pages of medical literature will be found many cases of laparotomy in children of this tender age which have terminated successfully, since Mr. Howard Marsh reported the first known successful case in 1875 in an infant six months old. Dr. Wiggin, in the *Medical Record* of January 18, 1896, has recorded sixty-four cases which he has collected of laparotomy undertaken for the relief of intussusception in infants under one year of age. Of these, twenty-one recovered and forty-three died, giving a mortality of 67.2 per cent.

Dr. Wiggin goes on to say: "If we count only the operations, successful and unsuccessful, that have been performed since the perfected technique of abdominal surgery has become generally known—say since 1889—we have a total of eighteen cases, of which fourteen were successful and four

unsuccessful, giving a still lower percentage of mortality, or 22.2 per cent., which the writer believes is a fair estimate of the risk to-day of abdominal section performed on a young infant for the relief of this disorder, if performed within the first forty-eight hours of the onset."

Dr. Wiggin has drawn his statistics from cases which have been recorded in the medical journals, and we all know the very natural tendency there is for surgeons to record successful cases and leave unsuccessful ones unpublished. To make the statistics of any value, we ought also to know how many cases each surgeon who records a successful case has operated on unsuccessfully.

With regard to the technique of the operation: The incision is best made in the median line, as it enables one to deal more readily with every part of the abdominal cavity. After the abdomen has been opened every care should be taken to prevent the escape of the intestines from the abdominal cavity; for a very considerable percentage of the mortality is due to this. If the intestines are allowed to escape they at once become distended with air, and there is always great difficulty in getting them back. Often a considerable amount of manipulation is necessary, which injures and bruises the intestines and leads to a fatal issue. The author therefore always makes a small incision into the abdominal cavity, only sufficiently large to admit of the introduction of two fingers, and as soon as the peritoneum is incised introduces a flat sponge so as to prevent the bulging of the intestine. He then passes a finger down by the side of the sponge and explores the abdomen. There is generally no difficulty in feeling the tumor if it is of the ileo-cæcal variety, in the right inguinal region, and when found the finger is carried along the course of the colon until the lowest limit of the tumor is reached. When this has been done the finger and thumb, which is now also introduced, grasps the intestine just below the tumor, and by gradually working along the colon and grasping successive portions of the gut, the intussusception is pushed backwards until it is finally reduced. All this is done entirely within the abdomen and without allowing the escape of a single coil of intestine. When reduction can be accomplished in this way it is done with a minimum amount of risk, but unfortunately it does not always happen that this plan succeeds. If the intussusception has existed for some time, so that adhesions have

formed, or if it is very acute, so that the intussusception is much swollen and congested, it will be found that the invagination cannot be reduced. Under these circumstances it will be necessary to enlarge the abdominal incision and bring the tumor up to the surface of the wound. This must be done with great care and gentleness, and all protrusion of the rest of the intestine must be avoided if possible. When the tumor has been brought into view the intestine is seized with the finger and thumb of the left hand below the invagination, so as to fix it, and then the intussusception is steadily pushed in an upward direction and in this way reduced. On no account should any attempt be made to reduce the invagination by traction on the entering tube.

Occasionally it happens that in cases of intussusception of long standing it is found that the invagination is irreducible; or it may happen that on opening the abdomen the intussusception is found to be in a state of incipient gangrene. What is to be done under these circumstances? There are three plans which may be pursued: 1. To make a longitudinal incision into the intussusciens and draw out the intussuscepted part, cut it off, and suture the intussusceptum and the intussusciens. 2. Resect the invaginated portion of gut and do an end-to-end anastomosis of the two cut ends of the gut. 3. Form an artificial anus.

The first mode of proceeding is best carried out by what is known as Maunsell's method. This consists in making a longitudinal incision in the intussusciens; through this is made to protrude, by gentle traction, the intussusceptum, until its neck appears outside the opening in the intussusciens. The base is then transfixed with two fine straight needles armed with horsehair, and the intussusceptum is amputated a quarter of an inch above the needles, leaving a stump beyond them. The needles are now pushed onwards, so that the sutures pass through the invaginated bowel, and the horsehair is then caught up and divided in the interior of the bowel, and the two ends tied on either side so as to unite the intussusceptum and intussusciens. These ends are left long and used as retractors to prevent the stump slipping back, while rows of sutures are being placed through the two cut surfaces of the bowel and tied. This having been done they are cut off short, the stump is pushed back into the bowel, and the longitudinal slit closed by a Lembert suture.

The second plan consists in excising the invagination and a wedge-shaped piece of the mesentery and approximating and uniting the two cut ends of the bowel. This is the ordinary operation for resection of a portion of the bowel, with which all are familiar. The cut ends after the resection may be joined in several different ways: by the Jobert-Lembert suture, by Maunsell's method, by Senn's plates, by Mayo Robson's or Allingham's bobbin, or by Murphy's button.

Of the third method to which he referred—the making of an artificial anus above the intussusception by opening the gut in this situation and attaching the margins of the opening to the external wound—little allusion is made, because it is not an operation of the present day. It was formerly advocated because it was the most rapid way of completing the operation, but now that we can do an end-to-end anastomosis as rapidly as we can make an artificial anus there seems to be no object in doing what is after all a very imperfect operation, and leaves the patient, if recovery results, in a sadly mutilated and distressing condition.

---

#### IODVASAGEN AS A SUBSTITUTE FOR INTERNAL ADMINISTRATION OF SALTS OF IODINE.

LEISTIKOW (*Monatshefte für Praktische Dermatologie*) calls attention to the fact that the mouth administration of the iodides of potassium, sodium or rubidium is attended with marked disadvantages, since it is liable to occasion catarrhal involvement of the mucous membrane of the mouth, nose, stomach, pharynx, and bronchial tubes, or rheumatoid pains, palpitation of the heart, and iodine dermatitis. Under such circumstances it has been the custom to abandon iodides, using mercury instead, or to employ enemata of potassium iodide. This latter method of administration is not one to be recommended, since even if the rectum tolerates the drug the systemic effects are the same as those produced by mouth administration. He has, however, had excellent results in the administration of the drug in the form of iodvasagen inunctions. In all he has employed it in twenty of his private cases. There are two preparations, one containing six, the other ten per cent. of iodine. The former is to be preferred, since it does not produce follicular inflammation. The application is made exactly as is the mercuric inunction—forty-five grains of iodvasagen are daily

rubbed in for ten minutes; the first day the left arm being selected; the second the right arm; the third the breast; the fourth the belly; the fifth the left leg; the sixth the right leg. The rubbings are continued for about three weeks. In four cases the rubbings had to be discontinued because of violent naso-pharyngeal catarrh. The remaining cases showed no reaction whatever, and the specific symptoms rapidly disappeared. From his experience Leistikow draws the conclusion that iodvasagen inunctions are an admirable substitute for the internal administration of the salts of iodine.

#### THE AMBULATORY TREATMENT OF FRACTURES OF THE LEG.

FISKE presents a *résumé* of the ambulatory treatment of fractures of the leg (*Medical News*, Feb. 13, 1897). He calls attention to the fact that after the discussion in Berlin in 1894 of the ambulatory treatment of fractures of the lower extremity considerable interest in the subject was aroused, and although nothing really new or novel was offered, still it has caused a somewhat more extended use of this method of treatment. The ambulatory treatment of leg-fractures seems to be regarded by some as new, and by others as merely the adoption of views that first found expression some thirty years ago. The method of which he speaks in this paper is in use in the Roosevelt Hospital fracture service, and at the time of its introduction by Dr. John McG. Woodbury was new as regards certain principles, namely, the time when the patient was instructed to walk on the injured limb, and the locomotion of the patient without the aid of crutches; and in speaking of the ambulatory treatment of fractures the writer has reference particularly to the large number of cases in the Roosevelt fracture service where the patient was allowed and encouraged to walk at once, without crutches or supporting braces other than the protective splint directly applied to the injured member.

The splint used in these cases is the plaster cast, so applied as to extend from the toe-tips up to and around the tuberosity of the tibia, so that in walking the greater portion of the weight of the body is supported by the circumference of the upper part of the cast. After reduction of any existing deformity, the limb being held in the proper position, the splint is applied as follows: Beginning at the toe-tips and extending to the knee-joint, the

limb is firmly and smoothly bandaged with an ordinary muslin roller; over this is applied the plaster-of-Paris cast. No padding with cotton is made use of, the object being to have the splint exert equal pressure at every point, and so provide absolute fixation. In many cases as soon as the plaster is perfectly hard the patient may walk without any other supporting apparatus. As a rule, however, he is instructed to keep his leg in the horizontal position for twenty-four hours, and if at the end of this time the splint is comfortable and there is no tendency of the toes to swell, he is allowed to walk.

In the treatment of any fracture there are certain important indications to be borne in mind. The surgeon must (1) reduce the deformity; (2) maintain such reduction; (3) fix the fragments and protect the limb; and (4) attend to the general condition of the patient. The last consideration is of especial importance, and emphasizes the desirability of keeping our fracture cases out of bed. It applies equally well to children, to adults, and to old men and women. Fiske cites the case of a man seventy-two years of age suffering from a Pott's fracture, who was up and about on the eighth day after the receipt of the injury, and able to walk without the aid of crutches or cane. These statements apply to all fractures, including even compound fractures, when observation for a few days has shown that no infection exists. In the ambulatory treatment of fractures the general condition of the patient is better maintained, less atrophy of the injured limb takes place, and the stiffness of joints in the neighborhood of the fracture is much less pronounced than in those cases which are confined during convalescence. The questions to be decided in considering the advisability of this method of treatment relate to the selection of cases, the form of apparatus to be used, the time when the patient is first permitted to walk on the splint, the duration of treatment, and the advantages gained and risks incurred.

The author has never seen a fracture of the leg which at some time during the healing process was not suitable for the ambulatory splint. There are many cases where the accompanying edema is excessive, and others where there is a considerable effusion of blood. In these cases the surgeon should apply equable pressure throughout, fix the fragments, raise the leg, and keep the patient in a recumbent position until the effusion is absorbed and the swelling disappears. The walking cast is then to be applied, and the patient is allowed

to be up and about. It is a great advantage to apply the plaster cast immediately after the receipt of the injury, and thus by the firm, even pressure which it exerts to prevent edema or effusion from occurring. In compound fractures the limb should be made thoroughly aseptic, an aseptic dressing applied, and the fragments fixed. If infection does not occur the ambulatory splint is applied later, and the patient then may begin to walk. When there is an extensive injury to soft parts the patient must be kept in the recumbent position, with the leg elevated, but in these cases the ambulatory splint should be applied as soon as the condition of the leg warrants it.

The plaster cast is the only one that has been used in the Roosevelt Hospital fracture service. The ordinary cast varies in thickness from one-eighth to one-fourth of an inch, being thickest at the ankle and at the upper circumference where it grasps the head of the tibia. The plaster-of-Paris used must be of the best quality. At Roosevelt Hospital use is made of two kinds of plaster bandages, one being the ordinary gauze roller impregnated with plaster-of-Paris, the other a stiff starch bandage similarly impregnated. A layer of the common plaster bandage is first applied, and this is followed by a layer of the starch plaster bandage; over this is built the cast with the common plaster-of-Paris bandages. By thoroughly incorporating these bandages into one mass a cast is made which is fairly light and yet possesses some elasticity, due to the starchy element; and so, while it affords absolute fixation, it is not liable to crack or break when the patient walks.

In an uncomplicated case when an immediate application of the cast has been made before the occurrence of edema, the patient is usually allowed to rest for twenty-four or forty-eight hours, and then if the toes are not swollen and the splint is comfortable he begins to walk. At first his gait will be awkward; he may be nervous and afraid to trust his weight on the plaster cast; but with a cane he will soon learn to balance himself, and in a short time he will require no support except that afforded by the splint.

As regards solid bony unions, in the great majority of cases no time is gained by this method of treatment. The after-treatment is considerably shortened, however, as the remaining stiffness is less and more easily relieved. The average length of time the splint has been worn is from twenty-eight to

thirty-five days. In a few cases it has been worn for six weeks, the time depending on the amount of callus thrown out and the completion of consolidation. After the removal of the splint the leg is douched alternately with hot or cold water several times a day, in conjunction with massage, until all stiffness has disappeared.

Some of the advantages of this form of treatment consist in the fact that the patient is kept up and about, less muscular atrophy occurs, there is less stiffness of adjacent joints, the period of after-treatment is considerably shortened, and the general health of the patient is maintained. It must also be remembered that the chances of hypostatic pneumonia occurring in elderly patients are much less if we keep them active. Quite a number of fractures of the leg have been treated in people addicted to the use of alcohol, and the reporter has never seen a case of delirium tremens occur when the ambulant splint was used from the first.

The chief risk is incurred during the application of the cast. To properly apply a cast of this kind requires a skilled operator and a skilled assistant. The importance of skilled assistance and intelligent co-operation is just as great to the surgeon in the reduction of the deformities attendant upon fractures as it is in the reduction of any other bone or joint deformity. The position of the limb, and skill in holding it during the application of the cast, are most important factors in connection with the success of this procedure. In oblique fractures the splint must be worn until the callus has been absorbed and the fragments have united firmly, so that there is no possibility of the upper fragment becoming displaced later by the weight of the body.

In many cases of Pott's fracture the deformity is so extreme and typical that a diagnosis is made at sight. In other cases there is no outward displacement, and very little swelling, and a correct diagnosis is arrived at only after a painstaking examination. The existing deformity is usually corrected easily by flexing the foot to a right angle and making extreme inversion. This position must be maintained until the splint has been applied and the plaster has set. Of the fifty-six cases of Pott's fracture the ambulatory splint was applied in thirty-eight instances during the first twenty-four hours; in eighteen cases the cast was applied from three to twenty-one days after receipt of the injury.

Fractures of the fibula are of very frequent occurrence. A fracture of the shaft fre-

quently shows little or no displacement, and as a rule simply requires the application of the plaster cast. Fractures of the lower end of the fibula frequently show some deformity, and may be accompanied by inward or outward displacement of the foot. A fracture of the lower end of the fibula accompanied by some outward displacement, but where the internal malleolus is intact, should be regarded as an incomplete Pott's fracture, and calls for the same treatment. Fractures of the lower end of the fibula with some inward displacement call for some eversion as well as flexion to a right angle before application of the plaster cast. Out of 110 fractures of the fibula, 101 were of the external malleolus or at the lower third. In 81 cases the ambulatory splint was used from the first. In the remaining cases of this group this treatment was inaugurated from two to twenty-three days from the time of injury, the cases including one compound fracture at the middle third of the bone where the walking splint was applied on the fourteenth day.

Fractures of the tibia are more serious, indicating as they do the receipt of greater violence, and may be accompanied by a considerable degree of shock. Many of the simple fractures do not show much displacement, and as a rule are readily put up in a correct position by having a good deal of extension made in the direction of the limb during the application of the cast. In the twenty-two fractures of the tibia, nine occurred at the lower third and thirteen at the middle third. Sixteen were treated from the first by this method, and six from five to eleven days after receipt of the injury, including one compound fracture on the fifth day.

Fractures of the tibia and fibula require the greatest care in putting them up properly. The surgeon must bear in mind the tendency toward a posterior sagging of the fragments during the application of the cast, and considerable extension must be maintained while this is being done. Of the fourteen cases of fracture of both bones, six were treated from the first by this method, and eight from the sixth to the fourteenth day. In fractures of the middle third of both bones, when there is a tendency toward displacement of the fragments, the splint should include the knee-joint and extend well up on the thigh. On the tenth day the bones will be pretty firmly glued together, callus will have been thrown out, and ossification will be under way. The splint is then removed, and if the

limb is in good order the ambulant splint is applied up to the head of the tibia.

The osteoclasia cases, twenty-four in number, are here considered because many of them have been most perfect examples of the ambulatory treatment of fractures of both bones about the middle third. They also show the value of the immediate application of the plaster cast, applied as it was without padding, and controlling or preventing the occurrence of edema and effusion. It has been common to see these little children after the first week stand and attempt to walk, and after that time they are always encouraged to do so.

The cases of non-union following fracture, eleven in number, which are presented were of no little interest, as several of the patients had been confined to bed for a considerable period. Not one case of fracture treated by the ambulatory method ended in this unfortunate way. The ambulant splint was applied to these cases, and the patients were encouraged to walk; if union did not occur within a reasonable time the fragments were thoroughly needled. This method has been very successful.

Two cases of the Trendelenburg-Hartley operation are considered, as they show the value of the ambulatory splint in compound fractures. On the tenth day as a rule the dressing was removed, the stitches taken out, and a new cast applied, and frequently by the fourteenth day the patient was able to walk very well. This is a very good showing when we bear in mind that a good-sized wedge had been removed from the tibia and a linear osteotomy performed on the fibula.

In 226 fractures of the leg the ambulatory cast was applied during the first twenty-four hours in 159 cases, about seventy per cent. of the total number.

#### *SYPHILITIC DISEASE OF THE HEART-WALL.*

SIDNEY PHILLIPS in *The Lancet* of January 23, 1897, presents an exhaustive paper with the above title, in which he summarizes his conclusions as follows: 1. Syphilis may produce gummata or general fibroid change. 2. Gummata in the left ventricle, except of very small size, are dangerous to life, and when near the apex of the left ventricle may cause sudden death. 3. Gummata in the left ventricle may be suspected if in an individual with syphilitic antecedents there occur signs of derangement of the action of the left ven-

tricle with symptoms of defective or embarrassed action, especially angina pectoris, tachycardia, syncopal or epileptiform attacks; or in the right ventricle when dyspnea otherwise unaccountable occurs. 4. Extreme feebleness of the heart without dilatation, gradually increasing, in young or middle-aged persons who have had syphilis, suggests syphilitic disease on the right side of the heart. 5. Dilatation of either side of the heart in syphilitic persons may result from syphilitic fibrosis. 6. Hypertrophy of the heart without ascertainable cause and without corresponding increase in strength of heart suggests syphilis. 7. Aneurism of the heart-wall may result from syphilitic local lesions, and may be fatal with or without rupturing. 8. It is probable that gummata and fibroid disease in early stages may be relieved or cured by the usual specific treatment, and there is every reason to believe that syphilitic lesions of the heart-wall are not less amenable to treatment in their early stages than syphilitic lesions elsewhere, though no cure can be expected where advanced tissue changes are already produced.

In what has been written attention has been devoted only to syphilitic disease of the heart-wall apart from valve disease. It is certain that the small number of cases given in the table must represent a much larger number of unrecorded fatal cases—cases in which no necropsy was performed, or the fibroid condition was not recognized or reported—and a very greatly larger number of cases of persons who have suffered from syphilitic heart lesions without their producing death. It is therefore certain that syphilitic heart disease is more common than is generally recognized. And its importance is the greater because it affects persons at an earlier age than the usual degenerative heart conditions, and may insidiously advance till it causes sudden death in persons in the prime of life and of apparent health.

There can be little doubt that syphilitic heart affections must affect the administration of anesthetics, more especially as a life-long disease like syphilis is apt to produce local conditions that not infrequently require operative interference. Certainly cases are brought in of death under an anesthetic from fatty disease of the heart, in which the chief evidence of that condition is that the patient died under an anesthetic; and at the moment of writing a case is recorded of death under the administration of the A. C. E. mixture in which "the right ventricle was found dilated,

with fatty infiltration of its walls; the left ventricle was also dilated and there was some fibrosis of its walls." Dr. Kirk found that chloroform, if we may judge from a few cases, is liable to give dangerous results in syphilitic subjects.

---

#### DOUBLE OVARIOTOMY AT THIRD MONTH: DELIVERY AT TERM.

PERRIER read before the Académie de Médecine, Paris, in January, notes of a case in which Mouchez, of Sens, removed both ovaries in a woman three months pregnant, for double cystic disease. The patient made a good recovery, and a live child was born at term. Numerous ovariectomies have been performed on pregnant women, but removal of both ovaries during gestation is unusual, not a dozen cases having been reported. Mouchez insists that operation as early as possible is indicated when double cystic disease is diagnosed during pregnancy. The danger of waiting is greater than the danger of operating.—*British Medical Journal*.

---

#### SOME RECENT ADVANCES IN THE TREATMENT OF ATROPHIC RHINITIS.

RALPH W. SEISS, in the *Medical News* of November 28, 1896, tells us that among drugs which have given good results as stimulants in the treatment of this disease thymol in his opinion still continues in the first rank; it may be used in watery solution with alcohol and glycerin, but is much better employed dissolved in one of the petroleum oils; albolene, glymol or benzoinol may be used, the thymol being in the proportion of from three to ten grains per ounce. The former strength can be borne by most patients, the latter only by a few in whom tolerance has been established by much previous treatment. Frontal headache, lacrymation, or a severe stinging sensation in the nose should always be regarded as indications for the use of a weaker solution. Numerous drugs may be usefully employed in combination with thymol, among them menthol, pine-needle oil, and eucalyptus, in the strength of from one to three per cent. Sanguinaria and galangal were once much used as stimulants in this disease, but they are exceedingly apt to act as severe irritants, and owing to this and their unpleasant taste have been largely abandoned. Next to thymol, euophen has given the greatest satisfaction in the writer's

hands; it may be used in the form of an ointment as above suggested, or of a dusting-powder in combination with stearate of zinc; or in advanced cases where marked stimulation is required the pure powdered eucalypten may be used. Although slightly less efficient than thymol in the average case, it suits some better, is always less painful, and its use may be regarded as one of the distinct advances in nasal therapeutics. Aristol, iodoform and allied compounds are also a benefit, but have more disadvantages than the one first named. Cinnamon oil has been shown to be the most decidedly antiseptic of the volatile oils, and is particularly valuable in conditions of nasal and pharyngeal sepsis; it may be used in the form of a spray, from three to ten per cent. being added to the ounce of albolene. It appears to be entirely non irritating, produces a grateful feeling in the nose, and its odor is pleasant and not persistent. Whichever oil-spray be employed it is essential that it be thoroughly applied to a perfectly clean mucous membrane, with a suitable apparatus, and with pressure of at least twenty-five pounds per inch.

Stimulation may be as easily overdone in cirrhotic catarrh by drugs as by mechanical means. MacDonald observes that "it is somewhat doubtful whether we are any more justified in stimulating the nasal mucous membrane in atrophic rhinitis than a cirrhotic liver." The warning and the pathological suggestion contained in this sentence are both exceedingly valuable. It cannot too often be reiterated that all violent measures in this disease defeat themselves by causing the very pathological processes which they are intended to cure. Purely surgical measures have but a limited value in cirrhotic catarrh; dead bone must be carefully removed, the minimum of disturbance of surrounding tissues being carefully observed; nasal spurs, or similar obstructions, should not be operated upon; and turbinated tissue should not be removed, except under cases of absolute necessity, the constant tendency to cicatrization and contraction in this disease never being lost sight of. He has seen several cases in which extensive intranasal operations had appeared to light up the atrophic process, and all operations on the turbinated tissues are to be regarded as at least unfortunate necessities. Jonathan Wright has had a similar experience, and forcibly points out how in vascular engorgement cauterization or other intranasal operation does not restore the efficiency of the damaged

muscular apparatus, but by the formation of a scar favors the tendency to fibrosis. The use of skin-grafts as suggested by Laborderie at first sight appears to be one of the most valuable surgical measures that has been brought forward in atrophic rhinitis, the very essential of the disease being the permanent loss of epithelium. Unfortunately the only available grafts which have been suggested are those which are covered by squamous epithelium, such as the intradigital membrane of the frog, whereas what is wanted is a membrane covered with columnar ciliated epithelium. The writer's efforts to graft such a membrane have been total failures, and it is doubtful whether it is possible to obtain this very desirable result. Laborderie claims that nearly half the grafts made from the skin of the frog take effect, and advises the use of from ten to twenty grafts in all advanced ulcerative cases. Even if this admirable result could be obtained by the average operator, a surface covered with pavement-cells and incapable of ridding itself of adherent mucus would be the effect, and the patient would be no better off than before.

The internal treatment of cirrhotic catarrh is not satisfactory. The only drug which can be considered to have the slightest specific effect is iodine. This may be given in the form of iron iodide or of potassium iodide, and certainly appears in some cases to lessen the tendency to inspiration and to exert a beneficial influence on the course of the disease. Tonics are of course needed in many cases, and hygienic measures are naturally of the first importance. Climatic change appears to arrest the disease in a certain proportion of cases, and should be tried when possible, especially after local treatment appears no longer beneficial.

Perhaps the most serious danger of advanced cases of nasal atrophy and suppuration is aural complications. A large proportion of cases have recurrent attacks of acute Eustachian salpingitis, a certain proportion of these going on to suppurative disease of the middle ear and perforation of the membrana tympani. Especially is this the case where the nasal douche, snuffing fluid from the hand, or similar measures in which hydrostatic pressure is brought to bear, have been employed. Colonies of streptococci are thus easily forced into the Eustachian tubes, with the result of setting up suppurative conditions extremely prejudicial to the welfare of the patient. With a view to the prevention

of these complications cleansing methods should always be by some such method as has been advised. Patients should also be carefully warned to avoid forcibly blowing the nose, as in this way the Eustachian tubes are frequently infected. The use of Politzer's inflation is even more dangerous, and should never be employed in cases of cirrhotic catarrh until absolute cleansing and antisepsis of the nasal cavities have been carried out. If suppurative salpingitis is already established the most satisfactory mode of treatment is by means of the Eustachian syringe-catheter. This should be introduced through the nose, and the folds of the tube carefully washed out with a warm, mild, antiseptic formula—boric acid and salt being commonly used by the writer. Treatment should be continued daily for some time, the tympanum being meanwhile carefully let alone, unless already actually diseased. If the middle ear be already involved antiseptic irrigation and, if necessary, an early paracentesis should be performed. Recurrent acute attacks of suppuration almost certainly result sooner or later in thickening of the drum and ankylosis of the ossicles in all neglected cases, and deafness and tinnitus aurium are almost the rule in such.

#### THE TREATMENT OF DIPHTHERIA WITH ANTITOXIN.

Additional testimony is constantly accumulating to establish beyond doubt the utility of antitoxin in the treatment of diphtheria. A recent contribution can be found in the report made by FURTH (*Münchener Medicinische Wochenschrift*, 1896, No. 29, p. 669) of 150 cases thus treated at the medical and surgical clinics of the University of Freiburg. This report is supplementary to a previous report of 100 cases treated in the same way. Of the 150 cases diphtheria bacilli were found in 123. In the remaining 27 the diagnosis was confirmed by subsequent tracheotomy; of these, 13 terminated fatally, and were examined post-mortem. Twelve cases in which diphtheria bacilli were not found were treated with antitoxin, but they are not included in these statistics. In 34 of the 123 cases streptococci also were found, but the examinations were made twenty hours after inoculation—a time thus unfavorable to the development of streptococci. In five children with laryngeal diphtheria, of whom three required tracheotomy and two died, diphtheria bacilli were cultivated from the pharynx, although this

was free from membrane, swelling, or redness. One of these children had measles also, so that the diagnosis was a matter of considerable significance. Of the 150 cases, 122 were uncomplicated and 28 complicated. The complications included measles (16), scarlatina (5), measles and scarlatina (2), measles and typhoid fever (1), and tuberculosis (4). Among the 122 uncomplicated cases there were 12 deaths (9.8 per cent.); tracheotomy was required in 26 cases (21.3 per cent.), with nine deaths (34.6 per cent.). Among the complicated cases there were 11 deaths (39 per cent.); tracheotomy was required in 9 cases (32 per cent.), with 6 deaths (66.6 per cent.). Of the 150 cases death occurred in 23 (15.3 per cent.).

Notwithstanding the coincidence of epidemics of measles and scarlet fever, the mortality was lower than in any previous year. The proportion of cases requiring tracheotomy was also smaller, and the mortality among these also lower. Over and above the complications the disease itself was in many instances of unusual severity. While in former periods the mortality in early life had varied from 60 to 100 per cent., in the present collection of cases there were only three deaths among nineteen children under two years of age, although eight of these cases required tracheotomy. The dose of antitoxin employed was larger than previously. Of the fatal cases two were septic, without involvement of the larynx. Both of these came under observation on the fourth day of the disease, and death took place in sixteen and sixty-eight hours respectively. In six cases death resulted from descending croup; all required tracheotomy. In two cases death was due to diffuse bronchopneumonia, after the local process had terminated. Finally, in two of the cases death resulted from paralysis of the heart on the sixth and forty-first days of observation respectively.—Editorial, *Medical News*, Nov. 28, 1896.

#### PALLIATIVE OPERATION FOR CANCER OF THE PROSTATE.

DESNOS (*L'Union Médicale*, No. 51, 1896) states that intervention is indicated when a patient is tortured by pains radiating to the perineum and the thighs. Pre-rectal incision is made, the prostate is freed from its adhesions, and the greater part of the tumor is resected. As a result of relief of pressure the pain is immediately relieved, and this persists.

APPENDICITIS ABSCESES IN POSITIONS  
REMOVED FROM THE IMMEDIATE  
NEIGHBORHOOD OF THE  
APPENDIX.

PIARD (*Gazette Médicale de Paris*, Dec. 19, 1896) writing on this topic states that a careful study of the literature shows that during the course of appendicitis abscess may form in regions other than those immediately surrounding the appendix; that these abscesses are found in the iliac cellular tissue, the peritoneal cavity, the anterior abdominal wall, the liver, the pleura, the lung, and in various more remote organs, such as the brain, the cord, the kidney, and the spleen. These abscesses are the expression of a diffuse infection either by the medium of the contaminated peritoneum or by the canals of the vessels of the appendix. They are rare and present all the varieties of local inflammation and general septic infection. This formation of secondary abscesses is an added reason for radical operation.

## Reviews.

---

A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS. Edited by Alfred Lee Loomis, M.D., LL.D., and William Gilman Thompson, M.D. Volume I: Infectious Diseases. Pp. 985.  
New York and Philadelphia: Lea Brothers & Co., 1897.

If the first volume of this System, purporting to be an exhaustive study of the diseases included within the domain of practical medicine, may be accepted as an indicator of the scientific value of the System in its entirety, we may well say that the work promises to surpass anything of the kind that has been presented to the profession within recent years. A glance at the list of contributors to this volume is in itself a sufficient guarantee of the value of the various sections, as there is not one who has not by his previous writings placed himself in a position to justify his selection to take part in the construction of such an important work as that now under consideration. While to do justice to each of the authors would be impossible within the limits of this short notice of the work, yet some of the articles are of such importance that they call for special comment.

The volume begins with an article upon malaria by William H. Welch and William S. Thayer, the former treating of the Definition, Synonyms, History and Parasitology of the affection, while the latter assumes the task of describing its Etiology, Pathological Anat-

omy, Symptoms, Diagnosis, Prognosis, and Treatment. This section is one of the most valuable in the volume; it represents in every particular the extent of our present-day knowledge of the disease, and a great deal is done by Dr. Welch in his classification of the malarial parasites to make clear much that has hitherto remained obscure in regard to the individuality of the organisms concerned in the production of the different varieties of the disease. There is undoubtedly still a great deal to be learned concerning the varieties of the *Hamatozoon malariae*, especially in the æstivo-autumnal form of the disease, but the deductions of Dr. Welch are to be welcomed as tending to lessen somewhat the obscurity that surrounds this subject. For the variety, or varieties, of organisms active in the production of the æstivo-autumnal form this writer suggests the name of *Hamatozoon falciparum*, indicating thereby one of its principal characteristics—viz., that it is a crescent-producing organism. Although crescents belong exclusively to the æstivo-autumnal parasites, yet their shape is not always crescentic or falciform, and to designate this parasite Welch prefers the adjective falciparum instead of that of falciforme as suggested by Antolisei and Angelini, which would indicate that the shape is always falciform. We believe that the majority will agree that this suggestion of Dr. Welch's is a happy one.

The section allotted to Dr. Thayer is handled in a thorough and painstaking manner and adds much to the value of the article.

Enteric Fever and Influenza, especially the former, have been assigned to J. C. Wilson. The article upon Enteric Fever is consistent in merit with recent publications of the author upon this subject, and confirms his position as an authority upon this disease. Of especial merit is the writer's description of the pathology and clinical course of the disease. The subdivision upon treatment is also thorough and represents his well known views concerning the management of the affection.

In this connection we cannot refrain from expressing the regret that the Editor has seen fit to interject into this article, as well as several others, what evidently are scraps and bits of his own personal experiences, and which he has supplemented by the insertion of numerous temperature charts that bear no part essential to the description of the disease as essayed by the author of the article. We consider that this serves no useful pur-

pose and tends only to mar the symmetry and evenness of the author's description.

The article on Dysentery, by Hamilton A. West, is an exhaustive study of the disease, the value of which is much enhanced by the insertion of colored plates by Councilman and Lafleur, previously published in the Johns Hopkins Hospital Reports.

The variolous diseases are described by William M. Welch, and the writer's familiarity with these affections is apparent upon every page. A number of reproduced photographs, taken from life, and representing the several types of variola, add greatly to the graphic description in the text.

William Hallock Park has been entrusted with the subject of Diphtheria, and in a comprehensive article of some sixty pages has succeeded in giving a description of the disease that will repay careful scrutiny. His conclusions regarding the diphtheria antitoxin are extremely emphatic and bear out the earlier anticipations as to the curative value of this agent. This is especially gratifying in view of the recent attempts in certain quarters to cast a doubt upon the efficacy of antitoxin treatment and thus to initiate a reaction against its employment.

The subject of Tuberculosis, by Osler, has been handled in such a way as only this distinguished pathologist and clinician is capable of doing. In many respects the general arrangement of the article is similar to that upon the same subject in the writer's *Practice of Medicine*, which will ever hold a place as a classical description of this infection.

It is impossible to do justice, save in an extended review, to the many other articles of great merit contained in this volume. The work is most ably edited, the assignment of the various sections has been made with great judgment, and there is lacking in an extraordinary degree that want of continuity and evenness that constitute such striking defects in many of the "Systems" it has been our duty to review.

The preparation of the Index, the quality of the paper used, as well as the printing, and, in fact, the work of the publisher in general, leave nothing to be desired.

We can warmly recommend the book as a standard work of reference.

HIGH ALTITUDES FOR CONSUMPTIVES. By A. Edgar Tussey, M.D.

Philadelphia: P. Blakiston, Son & Co., 1896.

This is a small octavo volume of less than 150 pages devoted to the subject named in its title-page. The author tells us that he

owes the profession an apology for offering this book to them, which is not a very encouraging statement for the reviewer to find in the first line of his Preface, for a book that is of any value needs no apology. The book is written in an easy, somewhat non-medical style, and is perhaps quite as well suited to lay reading as to medical reading. Now and then through its pages we find a quotation from Emerson or a dash of poetry, and the author breaks into an expression of sentiment in description, such as follows: "The gnarled and storm-developed giant of the open landscape became so in virtue of the necessity which was imposed upon it to maintain its life under numerous difficulties." We presume that the giant referred to is the oak, but as the words we have quoted form the beginning of the paragraph such a conclusion is only a supposition. Any book which tends to familiarize physicians with the real uses of climate in the treatment of disease is of value, but this one is hardly sufficiently exhaustive to be considered as a competent authority to govern the remedial applications of climate.

INJURIES AND DISEASES OF THE EAR: BEING REPRINTS OF PAPERS UPON OTOTOLOGY. By MacLeod Yearsley, M.D.

London: The Rebman Publishing Co., Limited, 1897.

This is a tiny volume of forty pages, containing many references to current literature and dealing with the following practical subjects: Artificial Membrana Tympani, Foreign Bodies in the Ear and Their Treatment, What Not to Do in Diseases of the Ear, The Use of the Pneumatic Aural Speculum, The Care of the Ear in Children, and Aural Reflexes.

Nearly all the material in the volume comes from the pages of *The Medical Times* and *Pediatrics*.

LECTURES ON RENAL AND URINARY DISEASES. By Robert Saundby, M.D. Copiously illustrated. Second Edition.

Philadelphia: W. B. Saunders, 1897.

There is probably no writer in the English language who is better or more favorably known in connection with the subjects dealt with in this volume than is Dr. Saundby, of Birmingham. The volume in reality consists of a reprint of a series of lectures delivered by Dr. Saundby, but to these lectures have now been added in the second edition much valuable information derived from bibliographical and statistical research. The volume as it stands to-day is probably the best brief summary of what we know concerning these

subjects of any that can be obtained. Every important chapter closes with a fairly copious and certainly representative bibliography of the subject which has been discussed, so that the reader who desires to seek further information can readily turn to more exhaustive and complete descriptions of the disease.

Those who are familiar with the interesting summaries published from time to time in the *Birmingham Medical Review* and in other publications to which Dr. Saundby contributes, will be anxious to obtain these lectures in book form.

**A MANUAL OF THE PRACTICE OF MEDICINE PREPARED ESPECIALLY FOR STUDENTS.** By A. A. Stevens, A.M., M.D. Fourth Edition, revised and enlarged. Philadelphia: W. B. Saunders, 1897.

This book, which has just been received from the publisher, is dated according to the Preface of the fourth edition July, 1896. We have already favorably reviewed in earlier issues of the *THERAPEUTIC GAZETTE* previous editions of this little manual. In this edition we are told by the author that he has rewritten several of the articles and also that two Italian physicians are translating the volume into their language. To those students who desire a very succinct and brief account of practical medicine, we can cordially recommend this little handbook.

**A MANUAL OF PHYSIOLOGY WITH PRACTICAL EXERCISES.** By G. N. Stewart, M.A., D.Sc., M.D. Philadelphia: W. B. Saunders, 1897.

That a good, concise, and fairly practical book on Physiology was needed in the medical literature of the day is shown by the cordial reception which has been accorded to the English edition of Dr. Stewart's book. The present volume is an American reprint of the same, and while it bears the date of 1897 it contains a Preface dated September, 1895, which is the date of the Preface in the English version. Dr. Stewart is well known as one of the younger physiologists who has already done good work in this important branch of medical science, and his success in teaching in Cleveland, Ohio, has proved that he has the ability of transmitting his knowledge to the student who desires to receive it. This ability shows itself upon almost every page of the volume before us, which is copiously illustrated and contains a number of colored plates which are more than usually good. There are also many illustrations devoted to the elucidation of descriptions of apparatus and records obtained from such apparatus, and the proper amount of infor-

mation is given to permit the volume to be used as a laboratory manual as well as a text-book. We doubt not that Dr. Stewart's book will continue to be considered one of the most popular text-books of the day.

**BRAITHWAITE'S RETROSPECT OF MEDICINE.** Volume CXIV, July to December, 1896.

This volume of Braithwaite's *Retrospect* closely resembles all previous volumes of this well known publication, which seeks to provide the busy practitioner with a summary of current medical literature. Those who have already found the usefulness of the publication will be glad to know that the one hundred and fourteenth volume has been issued.

**A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS.** In Photo-lithochromes from Models in the Museum of the Saint Louis Hospital, Paris. With Explanatory Woodcuts and Text. By Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Feulard, and L. Jacquet. Edited and Annotated by J. J. Pringle, M.B., F.R.C.P. Part VII.

London: The Rebman Publishing Co. Philadelphia: W. B. Saunders, 1897.

The photo-lithochromes (No. 7) in this series represent Eruption from Bromide of Potassium; Hypertrophic Papular Syphilides; Rupial and Early Gangrenous Syphilides, an illustration of particular beauty and value; of Gangrenous Tubercular Syphilide and Gangrenous Gumma.

The text is devoted not only to the diagnosis and clinical features of these eruptions, but takes up the subject of treatment in a thoroughly practical way.

**ROENTGEN RAYS AND THE PHENOMENA OF THE ANODE AND CATHODE: PRINCIPLES, APPLICATIONS, AND THEORIES.** By Edward P. Thompson, M.E., E.E. With a concluding chapter by Prof. William A. Anthony. Profusely illustrated.

New York: D. Van Ostend, 1896.

The title of this book describes its contents exactly, and to those who desire to become *au fait* with everything in connection with this most interesting subject it will convey, as perhaps does no other work in the English language, accurate, scientific, and yet readily understood statements in regard to the production of the Roentgen ray and the means for its application and employment. The latter part of the book is quite copiously illustrated by many skiagraphs dealing with medical and surgical topics. Altogether it contains nearly 200 pages, and its author is to be congratulated upon the production of so useful a manual concerning so interesting a topic.

**SYRINGOMYELIA.** An Essay to which was awarded the Alvarenga Prize of the College of Physicians of Philadelphia for the year 1895. By Guy Hinsdale, M.D.

This is a brief brochure of over seventy pages, including the bibliography, upon that rather rare form of nervous disease which gives it its title. It is quite freely illustrated and its text provides us with one of the best accounts of the affection which can be found in literature. Certainly the honor of winning the Alvarenga Prize has been increased rather than decreased by its award to this evidence of literary industry. No less than 388 references to the literature of the subject close the volume.

**ELEMENTARY BANDAGING AND SURGICAL DRESSING: WITH DIRECTIONS CONCERNING THE IMMEDIATE TREATMENT OF CASES OF EMERGENCY.** For the Use of Dressers and Nurses. By Walter Pye, F.R.C.S. Revised and in part rewritten by G. Bellingham Smith, F.R.C.S. Seventh Edition. Philadelphia: W. B. Saunders, 1897.

This book, as stated by Pye, is practically a reissue of the portions of his well known work on Surgical Handicraft which deal with bandaging, splinting, and the first treatment of cases of emergency. Thus it is a reprint, but so carefully selected, and issued in such a convenient form (indeed the book is small enough to be put in the waistcoat pocket) that it will no doubt be found serviceable to students, internes, and nurses.

There are many practical suggestions, such, for instance, as is found in Walker's method of applying a plaster jacket. This is as follows:

"The jacket may be put on while the patient is lying down flat, or better still, while extended on an inclined plane, with the hands raised backwards above the head and grasping a bar. This is known as 'Walker's Method.' To carry out this plan it is necessary to retard the setting of the plaster. This is effected by soaking the muslin bandages, into the interstices of which the plaster has been rubbed in the ordinary way, in a mixture of mucilage and water (about one ounce to a pint of water). When the roller bandages have been thoroughly moistened they are cut into lengths sufficient to go around the patient and overlap some inches in front. The several lengths are then arranged on the inclined plane so as to form a series of overlapping strips, in sufficient number to secure a three- or four-fold thickness everywhere.

"The cingle having been put on, and the pad adjusted, the patient is placed in the extended position over the strips of bandage,

which are then taken up one by one, and their ends crossed over the front of the chest and abdomen, like one loop and a bit of a figure-of-eight. If they have been properly placed it will be found that in this manner a well-fitting jacket of a somewhat hour-glass shape will be made, expanding above for the upper part of the thorax, and below to take hold of the pelvis.

"The patient should be allowed to lie still until the case sets, which it will do in three or four hours."

### LONDON LETTER.

BY RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.

Another orator has paid his tithe of homage to the memory of John Hunter: this year the mantle of Paget, Savory and other great men who have gone before, descended on Mr. Christopher Heath, lately President of the Royal College of Surgeons. The tendency of past orators has been to depict Hunter as a great anatomist, a learned physiologist, or a profound pathologist; but this year our portrait is of Hunter the Surgeon. In science, as in other spheres of action, coming events cast their shadows before them, and we are not surprised to find that Hunter foreshadowed so many of the giant strides of modern surgery. Thus in his lecture on "Injuries to the Head," Hunter showed himself to be far in advance of his contemporaries, with whom trephining the skull was a matter of routine. He writes: "In cases of fissure of the skull only, it may admit of dispute whether we are always to trepan. If there is no symptom of an injured brain, certainly it will not be necessary. It may not be necessary even when attended with symptoms of an injured brain, for the injury may only be from the concussion, and we never trepan for concussion." And again, in speaking of fractured patella, he says: "Before the year 1750 it was the practice to endeavor to bring the broken ends of the bones as near together as possible, with little or no motion allowed; but after that a fashion arose (for we have fashions in surgery as in everything else, arising perhaps from a person happening to do well who had not been treated in the old way) of letting the parts separate, and of not forbidding motion so strictly. But now caprice has, I believe, had its day, and

we are taught by reason and experience that the parts when cured should be as nearly as possible in their natural position." There is, however, a less modern flavor in the candor with which Hunter remarked of a patient, who died of fungus cerebri, after opening the dura mater: "He died, and I think it is probable I killed him by opening the dura mater." To Hunter too belongs the operation for cure of aneurism by applying a ligature at a distance from the sac, and in the museum of the College of Surgeons is the specimen of this historical case, obtained at the patient's death a year subsequently. The "Treatise on Venereal Diseases," though containing much of permanent value, was much marred by the essential misconception of the identity of the virus of syphilis and gonorrhea—a belief derived from experimental inoculation of himself with gonorrheal matter, accidentally contaminated with the discharge of a chancre. From the chapters on the "Supposed Consequences of Gonorrhea," Mr. Heath culls some very happy sentences. In describing the discharge of the natural mucus of the glands of the urethra Hunter writes: "The small glands of the urethra and Cowper's glands secrete a slimy mucus similar to the white of an egg, not coagulated. This seldom appears externally or flows from the urethra, but during the indulgence of lascivious thoughts, and is seldom or never attended to except by those who are either under apprehension of a gonorrhea coming on, or imagine the last infection is not gone off entirely, and are therefore kept in constant terror by this natural discharge." And in speaking of the discharge of the secretions of the prostate gland and vesiculæ seminales, Hunter says: "It is a discharge of mucus by the urethra, which generally comes away with the last drops of urine, especially if the bladder is irritable, and still more at the time of being at stool, particularly if the patient be constipated, for under such circumstances the straining or action of the muscles of these parts is more violent. It has generally been supposed that this discharge is semen, and the disease is called a seminal weakness; but it appears from many experiments and observations that the discharge is undoubtedly not semen." Mr. Heath tells us that he values this common sense teaching so highly that for years he has kept this page in Hunter's works doubled down, in order that he may read out an authoritative statement to those miserable persons who consult the surgeon from time to time for so-called "spermatorrhea."

The orator's valediction struck a note of timely foreboding: "Gentlemen," he said, "I cannot but view the future of this College with some anxiety. The great corporation is, I fear, on the high road to become something very unlike the Royal College of Surgeons of England, which has existed now for nearly a hundred years. Hitherto it has been regarded as the home of surgical science, and its funds have been devoted to the advance of the art of surgery by providing unrivaled opportunities for study in its museum and library. This College will, in my opinion, lose professional prestige and fall in public estimation if its funds should ever be diverted from these legitimate purposes in order to support the interests of individual members of the profession, however worthy in themselves. It will be a melancholy day for British surgery if ever this Royal College should become a gigantic protection society to fight the puny battles of its members, who may happen to come into collision with each other or with the public. It is to the Council, and to the Fellows who elect the Council, that we must look for the maintenance of that high professional position which the College has hitherto occupied, and for the furtherance of the art and science of surgery—*qua pro sunt omnibus artes.*"

At the Clinical Society of London Mr. Stephen Paget read a most interesting paper on "Voracious Hunger and Thirst after Injury or Disease of the Brain." He had collected notes of fourteen cases pointing to the existence of special centres of hunger and thirst close to the centres of speech, probably in the anterior extremity of the temporo-sphenoidal lobe. A short account was given of each case, including one in his own practice. Four of the patients had received a severe blow on the forehead; two had been struck on the side of the head; two had fallen heavily on the back of the head; two had presented signs of a fracture of the base; and one had fallen from a height, coming down in a sitting posture. In addition to these eleven cases of injury there were three cases of disease: one had abscess of the left temporo-sphenoidal lobe, one had a suppurating cyst in the right temporo-sphenoidal lobe; and one had embolism of the left side of the brain. Eight of the fourteen patients suffered from voracious appetite for solid food, without much thirst; three suffered both thirst and hunger; three had intense thirst without hunger. In none of them was

the primary injury or disease fatal. It was therefore pretty clear that the supposed centres for hunger and thirst were not situated in the immediate neighborhood of the so-called vital centres. Three of the patients had well marked aphasia; it was therefore probable that these centres lay close to the centre of speech, and not improbably connected with the olfactory centre, which some physiologists have located at the anterior extremity of the temporo-sphenoidal lobe. This hunger and thirst was of a degree far in excess of the normal hearty appetite of convalescence, and was not in any of these cases secondary to a traumatic diabetes. The therapeutic indication in this condition was extremely simple, for the patients suffered no obvious digestive disturbance in consequence of the enormous consumption of food and liquid. The voracious appetite lasted, as a rule, for many weeks or months, and then came to an end spontaneously.

Mr. Paget's paper suggests a number of interesting questions: We must admit that the evidence he adduces of localization is considerable; in nearly all the cases the main stress of the injury would have been on the temporo-sphenoidal lobe; but then we should expect the symptom to be present more often in the numerous cases of cerebral disease that affect this region directly or indirectly. Assuming, however, such a localization, what is the channel of connection with the stomach? Seemingly the gastric branches of the vagus. Such an affection comes quite into line with the gastric crises of locomotor ataxia, which Buzzard regards as evidence of a descending degeneration of the vagus, analogous to the optic neuritis of organic cerebral disease. If, however, we are to accept the occasional occurrence of aphasia as evidence of the adjacency of the speech centre, is it not a little remarkable that conversely hunger and thirst are so rarely associated with the many multiple cases of aphasia? On the other hand the condition may be the outcome of a general cerebral disturbance: thus voracity is a common symptom after an epileptic fit, but soon passes off; and thirst is still more common, both before and after the fit. Many epileptics, as the fit passes off, will swallow glass after glass of water in furious haste. In the discussion following the paper Dr. Colman suggested a happy parallelism to the cases of loss of memory, which after a fit lasts only a short time, but for much longer periods after a severe injury.

Dr. Stoker has been scandalizing the con-

servative propensities of the various medical societies by communications which at any rate have the merit of startling originality. He had observed that wounds containing staphylococci healed much more readily than those from which these organisms were absent, under treatment with oxygen. With the courage of experience—or of ignorance, as the elect would have it—he introduced these organisms into certain dilatory ulcers, and claims to have greatly accelerated their healing. Until more exact evidence, beyond all suspicion of experimental error, is to hand we must needs suspend judgment on the matter. If, on the other hand, we accept the proposition, the corollary is obvious, that we have been too indiscriminate in our antiseptic warfare by sparing neither harmful nor harmless microbes; or, indeed, we must postulate the beneficence of some that act as scavengers of organic debris, and flourish in a highly oxygenated atmosphere. The cases that were brought before the Harveian Society may be studied in detail to advantage, as they suggest not a few openings for error.

CASE I.—Mrs. B., aged fifty-one; had suffered from ulcerated legs for seven years; the ulcers commenced with an abrasion of the skin. She was first treated at the Chelsea Dispensary for three years with lotions, ointments and internal medicines. She lay up at home for three years while using these remedies. Afterwards she received similar treatment at St. George's Hospital for three or four years, but the ulcers never healed. She came into the Oxygen Home on December 28, 1896, with three large and two small ulcers. Under treatment with equal parts of oxygen and purified air, two of the large ulcers healed in eleven days, the other three partially. Accordingly these were inoculated with staphylococci, and by February 4 two were quite healed and one nearly so.

CASE II.—Mrs. H., aged thirty-eight; admitted to the Oxygen Home October 21, 1896. At Christmas, 1894, she was treated at St. George's Hospital for one small ulcer, which healed, but broke down again in July, 1895. In January, 1896, was treated at University College Hospital with improvement, but still the ulcer did not heal. In April, 1896, she returned to St. George's, and had lain up at home till admission. She was treated with equal parts of oxygen and air, and on November 23 the two small ulcers were quite healed. On December 21 a large ulcer was healed but for two small foci, which on January 22, 25, 26 and 27 were injected with

staphylococci, and by January 29 these were completely healed.

To these cases is appended a Bacteriological report by Messrs. Stoker and Dariey:

CASE I.—Before commencing the oxygen a cultivation was taken from the ulcer on agar-agar; after incubation it was found to contain a pure growth of staphylococcus *pyogenes citreus*.

Out of upwards of sixty cases examined, this was the first and only one in which a pure growth of staphylococcus was found previous to the commencement of oxygen treatment.

CASE II.—A cultivation taken before treatment with oxygen was found to contain bacillus *fluorescens* and staphylococcus *pyogenes albus*; the former disappeared after a few weeks.

As Dr. Stoker remarks, the main gist of these cases is to show the important relation between oxygen and staphylococci in promoting healing, but we cannot accept his conclusions as irreproachable. The central point is that whereas healing was only partial under treatment with oxygen alone, complete healing was induced on the accession of staphylococci; and if this were the whole case we should have to admit the corollary that there is some important interrelation of oxygen and staphylococci in promoting the healing process. In the first place, so far as the record shows, there was no absolute arrest of healing, but merely a retardation of the process, such as is usual at some period in the healing of most ulcers; then again there is no evidence by bacteriological testing of any activity of the staphylococci after inoculation. We would suggest that the better method would be to treat simultaneously two series of ulcers in which no tendency to healing is obvious, the one with oxygen alone, the other with oxygen and staphylococci combined, and to compare the results. Again, though we are convinced from inspection of cases that treatment with oxygen is most beneficial, we necessarily get a most inaccurate estimate of its value by contrasting cases so treated and in bed with cases treated by other methods but without perfect rest. Any one who knows the homes of the poor is well aware of the futility of "lying up at home." We would wish to see two series of cases treated side by side under the same conditions of rest and general hygiene—the one treated with oxygen, the other without. Our own experience of Unna's method is so highly satisfactory that we should hesi-

tate to recommend any other method to the family bread-winner. We have no wish to carp at Dr. Stoker's statements, but we should like more unimpeachable evidence.

In the *Indian Medical Lancet* Surgeon-Captain Roberts suggests the *rationale* of the domestic remedies for hiccough, which will probably not have struck many of our readers; nor will many be aware that these remedies were in use in the time of Plato. Hiccough is inspiratory spasm of the diaphragm, and in many diseases, particularly of the lungs and abdominal viscera, is a symptom of great prognostic import. The vagus by its laryngeal branches and the fifth nerves are the afferent nerves most intimately associated with respiration, while the glosso-pharyngeal exerts an inhibitory influence at the commencement of deglutition; hence the efficacy of such remedies as sipping a glass of water, eating a lump of sugar, and gargling; reflex inhibition of this kind is certainly more effectual than volitional, though sometimes simply holding the breath is sufficient to cut short an attack of hiccough.

In a recent article in the *National Review* Dr. Shadwell again conjures up the hydra-headed spectre of hidden disease to terrorize the lady cyclist. This time there is no talk of spinal concussion or curvature, none of irritable and dilated heart, but the familiar phantom of "nervous exhaustion" stalks abroad, seeking whom he may devour. The "*vera causa*," he writes, "seems to be in the extreme instability of the two-wheeled machine, which can never be left to itself for a single moment without dismounting; to ride it safely entails a double strain—a general one on the nerves and a particular one on the balancing centre." Now without following the writer into his minute discrimination between the fatigue of muscular effort and that of nerve exhaustion, which in cycling we cannot dissociate or distinguish, we would urge a common-sense view of the case. No doubt harm has accrued to some who have kept within the bounds of absolute excess, but we cannot for that reason admit that due moderation was observed; each rider must be a law to him or herself, and one cannot set up an absolute standard. But so universal is the consensus of opinion in favor of its general benefit, that we do not grudge these few hostages to the well-being of the majority. Cycling has often driven out the evil spirit of mental lassitude, which is the first stone in the building up of functional nervous disorder. No doubt the absorption of the fac-

ulties has done much to render the fatigue effects illusory, but none the less there comes a to-morrow of reckoning. Appetite has always seemed to us to be as sure a gauge as any of individual capacity, so accurately does the stomach reflect the general muscle state. To some there comes a fierce craving for food, and to these, as Homer to his heroes, we would award chinees of beef; but with others the stomach stubbornly revolts from food, and these have surely exceeded.

The ravages of venereal diseases among the British troops in India have at last gained the ear of the Government; and the reason seems to be that in the absence of preventive measures it has become a question of importance to the safety and integrity of the Empire, by its influence on the efficiency of the army in India. The statistics of the Principal Medical Officer's Report show that the total number invalidated for venereal diseases in a single year was 1663, so that nearly one-fifth of the whole strength were sent home on this account. The Secretary of State for India has appointed a Departmental Committee, under the presidency of Lord Onslow, to inquire into and report on the actual conditions. We are glad to see that the Indian Army Medical Staff is adequately represented on the Committee, as they alone have intimate knowledge of the extent of the evil. At a recent meeting of the Royal United Service Institution, Major-General Dashwood, in a statistical paper, brought the whole matter in all its bearings into public attention. Even if Government interference should fail to bring about a re-enactment of the Contagious Disease Acts, we may at least hope that the irrational and illogical distinction from the preventive measures applied to other infectious diseases may be removed. Meantime, at the Royal College of Physicians of London, it was resolved on the motion of Sir Dyce Duckworth, seconded by Sir William Priestley, M. P., "That a committee be appointed to advise the College on the desirability of making a formal declaration of opinion to the Government in favor of the re-enactment of the Contagious Diseases Acts in India, or of some such modification of them as may prevent the spread of contagious diseases;" and an influential body of Fellows was nominated by the President to serve on the committee.

The question of medical defense is still sorely exercising a certain section of the profession. For our own part we are disposed to dislike any measures of protection of a special char-

acter, as not likely to dignify the existing relation of doctor and patient; nor does the greater liability of the medical profession to false charges seem to us an adequate reason for a specially organized system of medical defense. If, however, such is destined to exist, there should clearly be no attempt to cast the burden of its working on any composite body, such as the General Medical Council or the British Medical Association—rather it should be of the nature of a purely private speculation, in no way involving the support of those who do not seek to participate in its privileges. The present state of affairs is due to the existence of two chief societies side by side, to the mutual disadvantage of either, crippling the efficiency each of the other, and rendering their common object nugatory. The recent suit of Cullingworth *vs.* Beattie has shown that medical men are not slow to succor their brethren in the hour of honorable distress.

The initial energy of the Hospital Reform Association has not yet blossomed out into even a hypothetical solution of the many difficulties that surround the matter. A close inquiry, under the auspices of the Charity Organization Society, into the social circumstances of those attending the out-patient department of one of our largest hospitals has led to the rather unexpected conclusion that only an infinitesimal fraction of this number can be said to be in a position to pay for private medical attendance. We are of course aware that the proportion at the special hospitals would in the nature of things be very much higher, but equally we believe that this finding would hold good for most of the large general hospitals. Nor can we blame this more well-to-do section for seeking at the special hospitals such advice as they cannot afford at the consulting-room of the specialist, and which it would be absurd to demand of the general practitioner with the many duties already resting on him. To meet such cases the hospitals should rather formulate some graduated scale of payment to be assessed in each case by a hospital almoner. It has also transpired that a very large proportion of out-patients require no medicine at all, but merely food and home care. It is true that the Pharmacopœia contains some excellent samples of the former commodity, but we venture to think that the necessary combination would be more effectively administered by referring such cases to the Poor-law. This would go far to reduce the unmanageable numbers, with which at

present our out-patient departments are hampered. Another less easily remediable problem is that the better and more expeditiously relief is administered to applicants, the larger becomes the demand on the work of that hospital, and so it results that the better the work is done the more are the workers hampered in its efficient performance—and this for the most part by the merest trivialities of accident and disease.

---

*PARIS LETTER.*

By A. R. TURNER, M.D. (PARIS).

During the next few days there will be tried in one of the Paris criminal courts a case which has already caused much comment in the medical and lay papers of this city.

A young woman, employed in one of the best known shops of Paris, died some days after the operation of curetting, and it was charged that the physician who performed the operation, as well as the physician who had sent the patient to him, were aware that she was pregnant, and that the operation was in fact a criminal abortion. What more than anything led people to this opinion was the fact that the paramour of the woman, an official of one of the towns situated just outside of Paris, shot himself on receiving a telegram containing the words "All is known."

It is charged that in reality the physician performing the operation, and who was at the head of a gynecological clinic, had more than once performed such operations. This event caused the greater interest from the fact that though comparatively young he occupied in the scientific world a certain position which, though not of the first place, was yet of some importance.

According to French custom the two physicians were arrested and kept in prison for some months. Only recently have they been allowed to communicate with their counsel. It is said that about 150 witnesses will be called.

One of the results of this scandal has been that two Syndicates or Associations of Physicians in Paris have been quarreling ever since. One calls itself "*Le Syndicat des Médecins de Paris*," the other "*Le Syndicat des Médecins de Paris et de la Seine*." One of the two accused physicians belongs to both of the Syndicates, the other to one only. One of the Syndicates passed a motion in which they said that their past knowl-

edge of their colleague inclined them to look upon him as innocent. Ever since then the two Syndicates have been requesting the public generally not to confound them, a thing which it is rather difficult not to do, on account of the similarity of their titles.

The interest in this case does not, however, depend upon the event itself so much as upon the current of public opinion which it reveals. Ever since the publication of the book "*Les Morticoles*," written by Leon Daùdet, a son of Alphonse Daùdet, the medical man has played in French literature, and above all in French contemporary drama, the rôle of villain, or at least what might be called a most unsympathetic part.

In a recent French play, "*L'Évasion*," out of several medical characters one only, the old country doctor, is not a fool or a scoundrel, two especially of the others being, one an old and highly placed physician who confesses in a moment of weakness that science is nothing, and another a younger man who seduces his female patients.

In all nations, and above all in France, public opinion moves from one extreme to another, not suddenly, however, but during a period of years; and it may be said that the rôle played by the physician in French literature is the exact opposite of the part given to him some fifty years ago, a good example of which may be found in Balzac's "*Le médecin de Campagne*."

An interesting article might indeed be written on the physician in the literature of all nations. Taking it altogether it would seem to me that he has either been drawn as a superhuman being, whose object in the book is to give expression to those reflections and sentiments which the author would in some cases express for himself, or else that he plays a comic rôle. Certainly the latter is what he does in certain of Thackeray's works, in "*Pendennis*" for instance, or even in the part of Dr. Filmer, if I remember the name correctly, in "*The Story of Philip*."

One modern author, Walter Besant, is rather fond of introducing medical men into his books; they usually, however, leave their shop outside, and indeed but one of them really lives—that is Mr. Brinjes, in "*The World Went Very Well Then*." With him we all sympathize, I think, notwithstanding the Devil which dwells in him; and by his side the other characters of the work are colorless.

Various forms of local tuberculosis have been treated by Lannelongue's sclerogenous

method, namely, by the introduction around the focus of disease of a few drops of a ten-per-cent. solution of zinc chloride.

Recently Dr. Lannelongue has tried it in an entirely different affection, namely, in the treatment of infantile hernia. The patient was a boy of fourteen years. After shaving and cleaning the region the hernia is to be reduced and carefully maintained so by an assistant, who compresses with his finger the internal inguinal orifice so as to cut off the peritoneal cavity from communication with the remainder of the canal. Next all the various elements of the spermatic cord should be gathered together. The cord being held with the left hand the right should plunge the needle of a hypodermic syringe filled with the chloride of zinc perpendicularly to the pubis and until the very bone is reached, when the point of the needle is turned under the posterior surface of the cord, and five drops of the solution are expelled into the fibrous tissue there situated.

Altogether eight or ten injections, or thirty to forty drops of the solution, are made into the fibrous tissue surrounding the cord. Some of the injections should be made at a lower or higher level than the others. An antiseptic dressing should be applied, and the child kept in bed eight days.

According to Dr. Lannelongue this operation is in nowise dangerous when carefully performed.

It has been claimed by a Russian military surgeon, N. V. Guéorguievsky, that the application of compresses dipped in chemically pure solution of bicarbonate of soda, of the strength of two per cent., arrests the production of pus and stops all inflammation much more rapidly than does the use of any of the antiseptic agents usually employed, such as carbolic acid or iodoform, etc. In several cases when all suppuration had ceased through the effect of the solution, the use of an iodoform ointment has caused it to appear once more.

## Notes and Queries.

---

### *THE WEATHER BUREAU IN ITS RELATION TO MEDICAL CLIMATOLOGY.*

The following resolutions were adopted by the Medical Society of Bernalillo County, New Mexico, at the meeting held January 15, 1897, and as they deal with an important climato-therapeutic subject we are glad to print them:

*Whereas*, This Society is impressed with a sense of the supreme value of the methods and work of the Weather Bureau of the United States in their relation to the science of Medical Climatology, as illustrated in the series of statistical tables published in Volume I, Annual Report for 1885, of the Signal Service (now Weather Bureau); said tables embracing all the data bearing upon nearly every meteorological feature necessary to a complete determination of the climate of many points scattered over the whole of the United States, so far as these data had accumulated up to the date of that Report; and

*Whereas*, The value of these tables would be greatly enhanced by working into them the data accumulated in the course of the eleven years which have elapsed since 1885, and a volume of immense value to the medical profession might be produced by appending to these tables, brought up to date, some account of the topography, geological formation, natural drainage, nature and source of water supply, vicinity of mineral springs, etc., etc., at each station where observations are taken; therefore

*Be it Resolved*, By the Medical Society of Bernalillo County, New Mexico, that the Chief of the Weather Bureau of the United States be respectfully requested to take this matter into consideration; that the American Climatological Association be requested to co-operate with the Weather Bureau through a committee appointed for that purpose, if mutually agreeable; that copies of these resolutions be transmitted to the Chief of the Weather Bureau, to the Surgeons-General of the Army, Navy, and Marine Hospital Service, to at least three of the principal medical journals of the United States, to the American Public Health Association and the American Medical Association, and to every State Medical Association in the United States, and their co-operation invited.

### *INTUSSUSCEPTION IN CHILDREN.*

In the hope of obtaining statistics which may prove of value in determining the true mortality of intussusception in children, the undersigned has endeavored to make a collection of unpublished cases, and with this end in view has sent several hundred letters to physicians in general practice. The greater number of these have had no experience. It is in the hope that some of the readers of the GAZETTE may have seen such cases that the appended questions are published. Answers will be very greatly appreciated by Dr. Edward Martin, 415 South Fifteenth Street, Philadelphia.

Seen by Dr..... In personal practice..... In consultation..... Age of patients..... Cause of intussusception (polyp?)..... Symptoms—Tumor..... Passage of bloody mucus..... Tenesmus..... Vomiting..... Intense pain..... Treatment—Medical..... Result..... Mechanical (injection of air..... water..... massage.....) Result..... Period elapsing from first symptom to mechanical treatment..... Treatment—Operative (Disinvagination through abdominal opening.....) Result..... Resection..... Result..... Seat of invagination..... Amount of bowel resected..... Method of joining intestines..... Period elapsing from the first symptom to the time of operation..... Results of autopsies.....

Further details not covered by the above headings will be gladly received, such as recovery with passage of slough, etc.

### THE CUMULATIVE ACTION OF DIGI- TALIS.\*

BY H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College of  
Philadelphia.

The most important point in beginning this article is to consider what is meant by the term "cumulative action of digitalis." By this term I mean the more or less sudden development of an irregular action of the heart in a person who has taken large and

repeated doses of digitalis, with a correspond-  
ing irregular, hobbling pulse and, if the effects  
are severe, vomiting, feebleness, and a sensa-  
tion of cardiac distress as additional symp-  
toms. These symptoms may come on while  
the patient is lying still, but are more fre-  
quently initiated by the patient sitting up-  
right or moving in such a way as to increase  
the work of the heart and vaso-motor system.  
When bodily quiet has been maintained by  
rest in bed for some days or hours the onset  
is usually sudden, but when the patient has  
kept on his feet the symptoms may come on  
more gradually. These symptoms are ap-  
parently due to the fact that the drug is  
given in such amounts and so frequently that  
it accumulates in the body; or if the drug

\* A paper read before the Association of American  
Physicians at the Congress of Physicians and Surgeons,  
Washington, May, 1897.

itself does not accumulate its effects accumulate, so that before the effect produced by one dose has passed by the effect of another is superimposed upon it. In the belief that digitalis has this cumulative effect the writer of course does not stand alone, for nearly all authors speak of it, and many of the profession believe in the possibility of its occurrence even if they have not met with it. Thus, Soullier (*Traité de Thérapeutique et de Pharm.*, Paris, 1895) says that digitalis is one of those drugs which possess the curious phenomena of accumulative effect, which necessitates the suspension of the remedy for eight days after it has been given eight days, and quotes Lepine as never using it on consecutive days. Waring in his "Therapeutics" says that digitalis when given in small, long-continued doses is apt to accumulate in the system and suddenly induce poisonous and even fatal effects. On the other hand, there seems to be some doubt as to whether we all have exactly the same idea of what we mean by this term, and some authors—and they are not a few—assert that a cumulative action does not occur. Thus Beaumont Small, in the "Reference Handbook of Medical Science," supplementary volume, expresses this idea, and Bartholow "agrees in opinion with those who hold that digitalis is not a cumulative poison in the sense in which this term was formerly used." On the other hand he admits that "doses of digitalis frequently repeated one after another, so that the effect of one is added to those before given, will certainly produce toxic symptoms," as will all other poisons used as medicines.

It seems to me that this is to a great extent exactly what happens in those cases in which what I call "cumulative effects" take place, and I do not believe that digitalis possesses any uncanny cumulative power of an extraordinary kind. On the other hand I do believe, not only from experience but from its known action given in small doses in all cases, that the ground for the assertion that digitalis is peculiarly apt to cause a cumulative result is very firm. In the administration of remedies we are not sufficiently governed by the speed of their absorption and elimination, and particularly is this true of digitalis. Again, we are apt to overlook the fact that certain drugs produce an effect which is prolonged. This is also particularly true of digitalis, for not only does its influence last for several hours but often for several days. Again, there are certain states of

the body which hinder absorption for a time and delay elimination, and also prevent this drug from acting while in the blood; as gastric atony in the first case, renal spasm or disease in the second, and fever in the third. In other words, while it is true that any drug has a cumulative effect when given too often, it is also true that digitalis can more readily be given too often than many other drugs. Again, the very physiological effect of digitalis tends to make it accumulate, for as Brunton points out, digitalin when taken for several days causes a decrease in the flow of urine, and this is due to spasm of the renal blood-vessels, which may be so great as to cause suppression of urine.

It therefore stands to reason that the frequent repetition of full doses must lead to its accumulation in the body, for the supply is greater than the amount eliminated. Such an accumulation with the production of a profound effect is met with when any drug which is slowly eliminated is given frequently in full doses; as for example in the case of bromide of potassium, where with each succeeding day and dose, the dose being the same, the sedative effects are more marked. Waring asserts that the bromides are sometimes taken in large doses for several days without effect, and thus a cumulative effect comes on.

In this case, however, the effects are gradually increased and the physician can measure the depth of the influence of the drug more accurately than when digitalis is given, for a peculiarity of the overaction of digitalis is that the symptoms entirely absent one moment are suddenly developed the next by some change in posture. Thus Brunton has pointed out that in many cases of heart disease the patient is much benefited by full doses of digitalis, but that it is dangerous for that patient to suddenly stand erect lest he have an attack of cardiac syncope due to the upsetting of the circulatory balance when it is under the influence of digitalis.

What the cause of this is we do not know. It is certainly not due to weakness, for the cardiac beats when they occur are in themselves more forcible than in health. The probable explanation of this peculiar cardiac irregularity lies in a disturbance of the co-ordinating apparatus of the various parts of the heart muscle. By this the author does not refer to the so-called co-ordinating centre of Kronecker and Schmey, which probably does not exist, but to the changes which may take place in the so-called "contraction wave"

which begins in the normal heart at the great veins and passes from them through the auricular walls to the walls of the ventricles. It has been found by Wooldridge and by Tigerstadt that if the auricles and ventricles be separated by a ligature or clamp they still continue beating, but no longer do so synchronously; or in other words the centres of each set of walls act independently of the others. The irregular action of the heart under digitalis is probably dependent upon this disassociation of its parts, and this theory is still further substantiated by the experiments of Roy and Adami, who have proved that independent contraction of the various parts of the heart can be produced by stimulation of the peripheral end of the cut vagus, a part of the nerve which is stimulated by digitalis in these large doses which we have been considering.

The reason therefore that the cumulative action of digitalis is more noteworthy than that of other drugs is that this effect is more apt to occur and to occur suddenly, and that it does not develop premonitory symptoms which force themselves as warnings upon the physician who is careless in its use or does not know the susceptibility of his patient.

That the symptoms to which the term "cumulative effect" is applied are practically identical seems proved by general consensus of opinion regarding them. Thus Von der Heide agrees with Withering (*An Account of the Foxglove and Some of its Medical Uses*, 1785) that two sets of phenomena take place: first, abnormal cardiac slowing, an irregularity, smallness and rapidity of the pulse after large doses; and second, vertigo, nausea, cramps, and sleeplessness. Husemann speaks of these circulatory and nervous effects, and of the slow, small and intermittent pulse; and as Edes says, most authors intend by the use of this phrase "cumulative action" to denote the sudden supervention of toxic symptoms, and in most cases a rapid, or at any rate a feeble and irregular, pulse.

Again, we find in Soullier's *Thérapeutique* (*loc. cit.*), published in Paris in 1895, that the dominant symptoms of digitalism, or that condition resulting from the overuse of this drug, are gastro-intestinal disorders, nausea and vomiting, cold sweats and general malaise. The pulse is exceedingly slow and filiform, and finally arrhythmical. Sometimes convulsions, dilated pupils and respiratory oppression are met with, and this condition arises from the retardation of the

absorption of the first doses of the drug. Reil states that the symptoms consist in pain in the epigastrium, nausea, great feebleness, amblyopia, and a feeling of weight in the head. Durozicz (*Académie de Médecine*, Mai 27, 1879) mentions the abuse of the alcoholic preparations of digitalis, and after naming a somewhat similar train of symptoms as already given as resulting from overdoses, he states that symptoms simulating meningitis may occur. Trousseau has also pointed out that full doses produce hallucinations, delirium, and a slow pulse of 32; and this is endorsed by Peter (*Bull. de Thérap.*, 1883, p. 108). The statements of Durozicz, Trousseau and Peter refer rather to poisoning than to effects resulting from cumulation, but it is of interest to note that the symptoms are much the same. It is also of interest to note that Raymond Tripiér (*Revue de Médecine*, 1883, 1884, 1885) points out that in some persons digitalis causes a slow pulse, syncope or epileptiform attacks, cardiac arrhythmia or bigeminal pulse, digestive disturbance, and pains resembling those of rheumatism in the limbs. It is evident therefore that the circulatory disorders under digitalis are practically identical whether a poisonous dose be taken at once; or it accumulates slowly and is then all absorbed, which is practically equivalent to one large poisonous dose; or that a person with an idiosyncrasy is poisoned by a dose which would not poison an ordinary individual. Soullier goes so far as to state that in the presence of digitalin we should institute treatment consisting of coffee, or caffeine, and strychnine.

In order that I might obtain a consensus of opinion from those best able to speak of this matter in an authoritative manner I sent the following series of questions to a large number of eminent practitioners and teachers, and have drawn the following information from their replies:

These gentlemen were: I. E. Atkinson, M.D., Professor of Therapeutics in the University of Maryland, Baltimore; F. C. Shattuck, M.D., Professor of Clinical Medicine in Harvard University, Boston; H. C. Wood, M.D., Professor of Therapeutics in the University of Pennsylvania, Philadelphia; W. H. Thomson, M.D., Professor of Therapeutics in the University of the City of New York; Abraham Jacobi, M.D., Professor of Diseases of Children in Columbia College, New York; James C. Wilson, M.D., Professor of the Practice of Medicine in Jefferson Medical College

of Philadelphia; Edward G. Janeway, M.D., formerly Professor of the Practice of Medicine in Bellevue Hospital Medical College; James Tyson, M.D., Professor of Clinical Medicine in the University of Pennsylvania; James T. Whittaker, Professor of the Practice of Medicine in the Medical College of Ohio; Dr. John H. Musser, Assistant Professor of Clinical Medicine in the University of Pennsylvania; Dr. T. Lauder Brunton of London; Dr. G. L. Peabody, Professor of Materia Medica and Therapeutics in the Medical Department of Columbia College; Dr. A. D. Blackader, Professor of Materia Medica and Therapeutics in McGill University, Montreal.

1. Do you believe in the possibility of, or have you met with, the so-called cumulative action of digitalis?

2. If so, under what conditions has it occurred as to disease, dosage, and age of patient? Or, in other words, what do you think predisposes to the development of these effects?

3. If you have met with it, what have been its chief manifestations?

4. What preparation of digitalis is most apt to produce this condition?

5. Has the presence of fever in your experience interfered seriously with the production of the physiological effects of digitalis?

In answer to Question 1—"Do you believe in the possibility of, or have you met with, the so-called cumulative action of digitalis?"—Dr. I. E. Atkinson, of Baltimore, states that he believes it possible for digitalis to produce cumulative effects, and he has seen two or three cases which have given very positive evidence of cumulative action.

Dr. Frederick C. Shattuck, of Boston, does not believe that digitalis possesses any more cumulative action than any other powerful drug which is given in full dose, particularly if there be idiosyncrasy present.

Dr. H. C. Wood, of Philadelphia, makes the following characteristic reply: "May I answer your inquiries in regard to the so-called 'cumulative action of digitalis' by saying that those who deny its existence are in a similar position to the famous King of Siam, who banished from his Court in deep disgrace the traveler who told him that he had seen the tops of rivers so solid that one could walk over them?"

A belief in the cumulative effect of digitalis is also recorded by Jacobi, who, when asked for an opinion, referred me to his "Therapeutics of Infancy and Childhood," in which he

says: "When large doses have been given for some time, accumulation of the effect takes place."

Dr. William H. Thomson has also met with this condition, and reports a case (see further on).

Dr. J. C. Wilson states that he has "never encountered the cumulative effects of digitalis."

Dr. Janeway replies that he has met with it.

Dr. Tyson states that he has met with it, although he does not believe that the term conveys an idea of the mode of its production.

Dr. Whittaker replies: "I do believe in the possibility, and have seen cases, of excessive action; whether it could be called cumulative or not I am not prepared to say from my own experience."

Dr. Musser has "never met with it and does not believe in it."

Dr. Lauder Brunton writes as follows: \*

MY DEAR HARE—I think that digitalis is cumulative; at any rate one certainly finds that after it is used for a while disagreeable symptoms occur. In my own experience these are generally shown first by the stomach in the form of nausea and vomiting. Just the other day I had a case in the Hospital where under the influence of digitalis great improvement occurred at first, then the pulse became more rapid and irregular. Instead of increasing the digitalis, as it was my first impulse to do, I knocked it off entirely and put the patient upon bismuth and soda, as I considered that the cardiac disturbance was the reflex from the stomach and that the gastric disturbance was due again to digitalis. The result appeared to show the correctness of my ideas, as the patient began to improve forthwith. I almost never give it in fever, so that I cannot answer your fifth question, nor can I say which preparation of digitalis is most apt to cause disturbance. The whole question is an exceedingly complicated one, and I regret I cannot give you more definite answers.

Dr. Peabody has never met with this phenomenon.

Dr. Blackader replies: "Yes; to some extent. Too frequently repeated in large doses it may accumulate in the system more rapidly than it is eliminated."

In reply to Question 2—"If so, under what conditions has it occurred as to disease, dosage, and age of patient; or, in other words, what do you think predisposes to the development of these effects?"—Dr. Atkinson states: "The cases have always been of organic heart trouble, when the patients have continued to take digitalis upon their own responsibility and for protracted periods—in one case for nearly three months."

Dr. Shattuck states: "I have seen the toxic—cumulative—effects of digitalis under the greatest variety of diseases, dosage, and age.

It has seemed to me, speaking broadly, that the greater the real necessity for the drug the less the danger of toxic action, and yet now and then I come across a case, as that mentioned, where a drug similar in its action to that of digitalis agrees while the latter distinctly disagrees. A predisposition to toxic effect depends, as it seems to me, on (a) ill-judged exhibition—giving the drug when it is not required—and (b) individual peculiarity not to be known beforehand."

Dr. Wood states in his book that it is connected with slow absorption and elimination, and is much more prone to occur when there is no diuretic effect. It is very apt to take place after tapping. Brunton thinks this effect is apt to take place at the development of crisis in fevers.

Dr. Janeway has met with the cumulative effect especially in Bright's disease, and possibly occasionally in pneumonia and in heart disease. He thinks the conditions produced by the continued use of the drug, and that pushing the drug when the heart has become slowed or irregular soon develops the cumulative effect.

Dr. Tyson says it occurs under circumstances which interfere with a prompt absorption of the drug, or at least its transmission to the centres in which it acts in producing its effects, followed by a sudden removal of such obstacle. Such removal is brought about by brisk purgation, by the removal of accumulations of fluid in the peritoneal or pleural cavities, and especially by a blood-letting practiced when such obstacle exists.

Dr. Whittaker says: "The excessive action has resulted from too long administration—that is, from use continued after the effects of the remedy had been obtained."

Dr. Blackader says: "Untoward symptoms are most apt to develop when the heart muscle is to any degree diseased."

In answer to Questions 3 and 4—"If you have met with it, what have been its chief manifestations? What preparation of digitalis is most apt to produce this condition?"—Dr. Atkinson says "the chief symptoms have been profound debility with a tendency towards syncope, nausea, very slow pulse while in a recumbent posture, becoming rapid and feeble upon exertion. He has no recollection or memoranda of effects upon the vision or kidneys. The urine was not suppressed. Recovery followed within a few days after the drug was abandoned. The dose had not been increased and was not large." His cases used the tincture.

Dr. Shattuck states: "The toxic effects as far as I have seen them—and they have occurred many times under my observation—are anorexia, nausea, vomiting, a weakened and irregular pulse, and diminution in the urine. The toxic effects depend on the purity of the drug rather than the preparation."

Dr. Wood also states (see also answer to Question 1) that sometimes the first marked symptom of this action is severe syncope, followed by paraplegia, vomiting, diarrhea, insensibility, and death. Usually, however, only the change in the pulse occurs if the drug is not pushed.

Dr. Wood reports: "A single case from my own experience will suffice: A woman was taking digitalis freely, with the hope of bringing about absorption of a pleuritic effusion; after many days no effect was manifest from the drug, until suddenly her pulse, which had been running about 90, fell to 75. The use of the digitalis was immediately discontinued. The next day the pulse was 60; the next day, 50; the next day, 40; with all the characteristics of over-digitalis action. It was nine or ten days before the pulse had regained its normal rate. In conclusion I see no reason for supposing that one preparation is more apt than another to accumulate."

Dr. W. H. Thomson, of New York, replies as follows: "I can report one unmistakable case of dangerous and specific symptoms of cumulative action of digitalis in a phthisical patient, female, aged 25, after taking Niemeyer's pill, one three times daily, containing one grain of powdered digitalis, for six days. There was no reason to suspect that the pills themselves had accumulated in the primæ viæ previous to the sudden onset of the symptoms, which were deathly nausea and vomiting continuing for eighteen hours, with very intermittent pulse. Every measure failed to stop the vomiting until half a grain of morphine was given subcutaneously, which then arrested it. Patient lived for two years afterwards without any similar experience. There was no renal element in this case."

Dr. Jacobi (*loc. cit.*) says the pulse becomes quite slow and irregular and vomiting sets in in this condition.

Dr. Janeway has found the chief manifestations of this state to be sudden death on exertion, and he adds: "I have in the past on several occasions made post-mortem examinations of persons who had been under treatment in hospital with digitalis who had dropped dead on going to the water-closet; also in pneumonia under treatment with digi-

talis some are inclined to hold sudden death due to digitalis. It is somewhat difficult to be certain in these cases."

Dr. Tyson replies "almost solely slowing of the pulse, at times to 40 or even less beats per minute." He does not think it is peculiar to any form of the drug, though he has met it most frequently when using the tincture.

Dr. Whittaker says: "The chief manifestation was the hard, slow pulse, with subsequent exhaustion of the heart, and paralysis. I have seen the condition only after the use of the infusion, which is usually given in larger dose."

In reply to Question 5—"Has the presence of fever in your experience interfered seriously with the production of the physiological effects of digitalis?"—Dr. Atkinson states as follows: "In my experience the presence of fever modifies the action of digitalis very profoundly; in the various febrile conditions in which the heart often shows evidence of failing (typhoid fever, pneumonia, etc.) digitalis is notably inferior to strychnine and alcohol, and indeed as a rule fails to influence either the frequency or force of the heart's action or to increase arterial tension. In my experience the febrile condition in great measure prevents the action of digitalis, as shown in the afebrile state."

Dr. Shattuck states: "I have thought that a febrile patient seemed less likely to be upset by digitalis—or evidently so. I may add that if I prescribe digitalis for a patient who cannot communicate with me promptly and whose condition is not urgent, I am apt to give the drug only twice a day at twelve-hour intervals. This is with the idea of diminishing the liability of toxic or unpleasant effects of the drug."

Dr. Thomson states: "In my opinion digitalis has no beneficial effect upon the heart when weakened by fever. In diphtheria its effect is most disastrous."

Dr. J. C. Wilson: "The effects of digitalis are not manifested in febrile cases in the same way nor to the same extent as in other conditions. This has appeared to me, however, to be due not so much to high temperature as to associated derangements, especially in part malnutrition of the heart muscle."

Dr. Janeway replies that in his experience the presence of fever "does not necessarily" interfere with the effects of digitalis.

Dr. Tyson replies: "I cannot say that I have observed such interference."

Dr. Whittaker says: "It seems to me that the presence of fever, by delaying the absorp-

tion of the remedy, interferes with its physiological effects."

Dr. Musser says that he has never secured physiological effect in the presence of fever.

Dr. Peabody thinks that fever does interfere with the effect of digitalis.

Dr. Blackader states that the presence of fever to some extent antagonizes the action of digitalis, and therefore demands a larger dose to produce the same physiological effects.

Reil has remarked upon the fact that cumulation occurs less frequently when digitaline is given than when the infusion is used, because he thinks that digitaline gives warning of its excessive effect, whereas the infusion does not.

It is interesting to note in connection with the answers to the last question, as to influence which the presence of fever exercises upon the action of digitalis, that almost every therapist recognizes that fever does prevent digitalis from acting. In my earliest days as a physician in charge of patients in the wards of a large hospital I noted this fact, and on searching for similar experience as recorded in literature I found both such experience and careful pharmacological research pointing to the truth of my observation. Thus as long ago as 1865 Thomas recorded the fact that digitalis does not act in certain cases of pneumonia, and Brunton and Cash then proved that the failure of the drug to slow the pulse depended upon the fact that the inhibitory action of the vagus centres, ordinarily stimulated by digitalis, is lessened by heat, and that the peripheral ends of the vagus are also depressed. A belief that this cause exists for the non-appearance of the physiological action of digitalis is expressed by Wood.

#### MALARIAL HEMATURIA.

By J. W. MEEK, M.D.,  
Camden, Ark.

In the October number of the THERAPEUTIC GAZETTE is a review of The American Text-book of Applied Therapeutics, and the reviewer criticises Dr. Dawson's treatment of malarial hematuria by the quinine method. In the December number appeared a criticism of Professor Tyson of Philadelphia for advocating a similar treatment in his Text-book of Medicine, recently issued.

I have not seen Dr. Dawson's article, but have read Professor Tyson's, and I desire, as one who has had some experience with this

malady, to add further *emphasis* to your criticism, and in the name of humanity to protest against a further promulgation of the idea that quinine is admissible in the successful treatment of this affection.

I know nothing of Dr. Dawson's opportunities for observing this disease; he may speak from personal observation or the contrary. Professor Tyson claims to have had considerable experience with the malady.

I will say this, that if quinine is curative of malarial hematuria in Philadelphia, it is certainly a disease very different from that occurring in Arkansas.

Malarial hematuria is, in North America, confined almost exclusively to the Southern or Southwestern States; moreover, it is rarely seen in cities, but is chiefly confined to rural districts. As a rule our ablest medical investigators live in the cities, and hence rarely see it. Furthermore, the men who write our text-books of medicine (I speak it to the shame of my Southern brethren) nearly all live in the North.

From this it will be seen that many of our best physicians, or at least our ablest scientific investigators, rarely see a case, and many of our text-book authors have perhaps never seen one. "Swamp doctors" as a rule do not write for publication, and the history of malarial hematuria has not been written by those who have met it face to face and engaged it in deadly combat.

It sounds very plausible to say that malarial hematuria is caused by the malarial parasite, and hence quinine is necessarily the remedy, but this species of reasoning affords but little consolation to the conscientious physician in the hour of humiliation and defeat; nor do the statistics of this treatment warrant the premise that the disease is essentially malarial in its origin. Professor Tyson says, page 72 of his text-book: "If quinine fails to break up the paroxysm of the mildest form, when administered as directed, the hematuria has an origin other than malarial." Now in my experience and that of many others it not only fails to arrest the paroxysm but aggravates every symptom, and adds very greatly to the mortality of the disease.

The diagnosis of some diseases is at times *only* positively made by the administration of certain remedies and an observance of the therapeutic action of the drug administered. Thus the curative action of mercury and iodide of potassium, administered in certain obscure affections, is considered positive proof of the specific nature of the malady thus cured,

and the immediately curative action of quinine is and should be proof of the malarial nature of the disease thus treated. Judged by this rule malarial hematuria cannot be classified as a strictly malarial disease.

It is to be regretted that there seems to have been no blood examinations by competent bacteriologists to determine the presence of the malarial parasite or other organism. A proper examination will probably discover a bacterium at present unknown.

The mortality from this disease is not so heavy as it was twenty years ago, and at that time it was treated almost exclusively by massive doses of quinine.

During the first ten years of my professional life I treated quite a number of cases with large doses of quinine—twenty, forty and sixty grains being given in twenty-four hours—and the mortality was at least fifty per cent. Since that time I have treated quite a number without quinine, and the mortality has been eighteen per cent. The cases treated without quinine were as severe as those treated with it.

Dr. Guise, of Mississippi, reports having seen about twenty-five cases treated with quinine, and a mortality of more than fifty per cent.; and he also reports four cases treated without quinine, all of which recovered. Four successful cases is too small a number to prove the success of any method, but twenty-five cases with a mortality of fifty per cent. would not encourage one to pursue that plan. Hyposulphite of sodium has in my hands and also in the hands of others proven decidedly curative in this affection, but in my experience it has proven of little value in other forms of malaria. This to my mind establishes another point against the malarial origin claimed. The disease undoubtedly occurs almost if not exclusively in malarial regions, and nearly always in persons who have shown previous evidence of malarial toxemia; but malaria may be only a Trojan horse by which the gates are unbarred to admit a more deadly foe to the citadel of life—the patient's blood.

In the THERAPEUTIC GAZETTE for July, 1892, Prof. H. A. Hare, of Philadelphia, has with a commendable zeal made an effort to collect the experience of medical men who have had to deal personally with this disease. It is to be regretted that such authors as Osler, Pepper and other justly eminent authorities have not done the same before giving the sanction of their text-books to the stereotyped treatment by quinine, etc.

Professor Hare has, in reply to his inquiries, received the following from physicians practicing in Texas, Mississippi, Georgia, and Alabama:

Nineteen physicians, whom he classes as "experienced," consider quinine "useful" in this disease, but twenty-eight—"experienced"—consider it "harmful." This gives a decided majority of "experienced" ones against its utility. Of course the reader can form no idea of the comparative abilities of these respondents. The replies from those whom he classes as "inexperienced" are largely in favor of quinine. The knowledge of the latter class has doubtless been gained from text-books, and it would appear from an analysis of the above replies that experience with the malady changes the views of a large majority.

It is not my intention to enter into a full description of this disease, nor into all the details of what I consider the proper treatment. My main object in inditing these lines is to lift up my "voice as of one crying in the wilderness" against the evil of advising the use of quinine in this disease. I am not an enemy of quinine in the abstract. I give it with a free hand—frequently thirty to forty grains per diem—with the happiest results in other maladies, but I desire to see the profession set the seal of their eternal reprobation on its abuse in malarial hematuria.

A few words in regard to the clinical history and treatment and I am done.

The subject has usually been suffering with an intermittent fever, and has almost invariably taken quinine the day he is attacked. A chill ushers in the attack; bloody urine appears in from one to three hours; febrile reaction is not usually above  $102^{\circ}$  or  $103^{\circ}$ . The skin and conjunctiva become intensely yellow in from two to six hours. There is constipation and great gastric irritability. The vomited matter is frequently green, and late in the disease becomes black—a "coffee-ground" color. Rigors frequently occur every six hours. The urine is usually at first increased in quantity, but later becomes scanty; it gives a heavy albuminous deposit from heat or nitric acid, and under the microscope shows blood casts and red blood-corpuscles. The jaundice is, judged by the rapidity of its progress, necessarily hematogenous. A complete obstruction of the common bile-duct could not produce such an immediate discoloration. Some subtle poison has gained entrance to the vital fluid—is breaking down the red blood-corpuscles—producing an explosive hemoglobine-

mia; hence the jaundice is due to pure hemoglobin in the blood. If this condition is not soon arrested the vital fluid becomes incapable of stimulating the nervous centres to a performance of their functions, vaso-motor paralysis occurs, the blood is emptied into the larger internal veins, and the patient is bled to death into his own blood-vessels. This is the disease as it occurs in Arkansas.

Some patients are stricken down as if by a blow and will die in spite of all remedies, but this class is fortunately small. In the *New Orleans Medical and Surgical Journal*, November, 1891, I concluded an article on the subject of malarial hematuria with the following recommendations, which I cannot now improve upon:

1. Give hyposulphite of sodium in drachm doses every two hours until the patient is thoroughly purged; then continue in smaller doses until the system is saturated with it.

2. Give morphine and atropine hypodermically, sufficient to quiet stomach; also blister the epigastrium if necessary.

3. Give an abundance of water to wash out the coagula that must necessarily accumulate in the urinary tubules after a hemorrhage.

Hot water or hot lemonade is frequently better borne by stomach than cold. Cupping over the loins is also to be recommended.

4. The diet should be mild. Fresh butter-milk is usually well borne by the stomach and is also a mild diuretic, and I have come to rely on it as an article of diet in this as in many other diseases.

5. Keep patient in a strictly recumbent posture.

I give hyposulphite of sodium in this affection for the following reasons:

- a. It is a stimulant to the hepatic secretion, causing in large doses abundant biliary secretion, and is also a valuable intestinal antiseptic.

- b. I believe that free sulphurous acid is disengaged in the blood, and that this agent is an antizymotic to such an extent that it destroys the micro-organism which is the real cause of the disease, and thus arrests the process of corpuscular disintegration.

---

#### REPORT OF A CASE OF PUERPERAL SEPTICEMIA TREATED WITH NUCLEIN.

BY HENRY M. JOY, M.D.,  
Grand Rapids, Mich.

The treatment of puerperal septicemia must of necessity be considered from two standpoints, namely, surgical and medical.

The first has for its consideration the removal or limitation as far as possible of the source from which the toxic elements are supplied to the blood, and the second the aiding of Nature in her efforts to overcome the poisons already in the system. In other words, to increase the antitoxic constituents

tex presenting. The case was conducted with the greatest possible antiseptic precautions, and labor was completed naturally in about six hours. The patient being out of the city I did not see her again until the morning of the sixth day, when I was hurriedly summoned to attend her. I found

#### GRAPHIC CLINICAL CHART. Reprinted by J. P. Cramer, M.D., M.A.

Clinical Notes

Pulse

*Pulse*

of the blood or to strengthen those constituents which are already present.

A report of the following case in connection with the fulfilment of the second indication will I think be of interest:

On December 10, 1896, I was called to attend Mrs. C. in her second confinement. I found the patient in good physical condition. The child was lying in second position, ver-

that the previous night she had had a severe chill lasting about an hour. At the time of my visit the temperature was 105°; pulse 150, feeble and thready. Abdomen greatly distended and very tender on pressure, skin icteric, and a condition of marked apathy denoting most profound sepsis. A vaginal douche of creolin solution was administered at once, followed by an intra-uterine douche

of the same solution. My attention having been called to the use of Parke, Davis & Co.'s nuclein in puerperal septicemia,\* and having had satisfactory results from its use in cases of surgical sepsis, I ordered one drachm of the five-per-cent. nuclein solution (P., D. & Co.'s) to be given internally every three hours. The day following the nurse in charge of the case reported a slight chill followed by a temperature of  $105^{\circ}$ , pulse 110, but general condition of patient somewhat improved.

Vaginal douches were given daily by the nurse, and nuclein continued as before. No recurrence of the chills occurred after the second day. The temperature remained approximately the same for six days, when it fell by crisis (see chart). Although during the first six days there was little variation in the height of the temperature, the daily remissions were marked, and the pulse continued to fall steadily and improve in quality, the general condition being one of progression. The patient's mental condition changed rapidly for the better, appetite returned, and the skin assumed its normal color.

Nuclein, then, is a remedy which aids us in fulfilling the second indication in the treatment of puerperal septicemia—*i. e.*, the strengthening of nature's antitoxic elements. It acts favorably and promptly upon leucocytosis, it causes no unpleasant complications or effects, it acts rapidly, and under its use the fetid discharges quickly diminish.

#### THE PASTEURIZATION OF MILK.†

By J. P. CROZER GRIFFITH, M.D.,

Clinical Professor of Diseases of Children in the University of Pennsylvania.

Sterilization of milk was practiced empirically long before much was known of its scientific principles. It has been known by mothers for years that milk was less liable to derange an infant's digestion if it was scalded before being used; and it has long been the practice of physicians to recommend the boiling of milk and the subsequent keeping of it on ice in order to prevent decomposition taking place. The preservation of milk by long boiling was recommended from a scientific standpoint by Solltman, Albu, Bertling, and others. So, too, the modification of this process, consisting in the steaming of milk in a water-bath, antedated the studies of Soxh-

let, and was advised by Röder, Hartmann, and others. The first, however, to devise a method both scientific and practical, for the sterilization of milk at the infant's home, appears to have been Soxhlet, writing in 1886. The characteristic of his method which distinguished it from any preceding one was that the milk for each feeding was sterilized in its separate bottle, and the number of bottles with their contents, sufficient to last the entire twenty-four hours, were all sterilized at once. By this plan was avoided the opening of a large vessel of sterilized milk in order to take out the amount required at different times, and the attendant danger of reinfection of the remaining milk. In all previous methods the milk was sterilized in bulk. Later sterilizers are all made on the Soxhlet principle. For practical purposes a single steaming in the sterilizer is sufficient, since the bottles will be placed on ice in any case afterwards as a matter of precaution, and the milk will be used within twenty-four hours. In very hot weather it is not a bad plan to resterilize in the evening the bottles which remain. Flügge has shown, too, that five minutes at a temperature of  $100^{\circ}$  C. ( $212^{\circ}$  F.) is as good as forty-five minutes; yet he recommends an exposure of ten minutes; and in practice a longer time is conveniently employed.

Now it is well known that boiled milk has a decidedly altered taste and odor, and it is certain that even milk sterilized in special apparatus will show this same alteration. But what is far more important is the fact that the heating of the milk to the boiling temperature produces chemical changes which may seriously affect its digestibility. Leeds found that a temperature of  $100^{\circ}$  C. coagulated some of the lactalbumen, while it rendered the casein less coagulable by rennet, and made it less easily acted upon by pepsin and pancreatin. In the case of many children this alteration appeared to make but little difference; in others, however, the assimilability of sterilized milk was certainly much diminished, and the infants did not appear to thrive upon it. These observations have been confirmed by others. The effort consequently has been made to discover a method by which the milk might be rendered free from germs and yet have its taste and digestibility unaffected.

Pasteur found in 1868 that wine exposed for a short time to a temperature of  $55^{\circ}$  C. ( $131^{\circ}$  F.) would not spoil. Later investigations based on this discovery have developed the method which now commonly goes by the

\* Boise: Treatment of Puerperal Septicemia.

† Read before the Philadelphia Pediatric Society.

name of pasteurization; this consisting in the exposure of milk or other liquids to a temperature ranging from 55° to 80° C. (131° to 176° F.) and followed by rapid cooling. As applied to milk it has been found that a temperature of 75° or 80° C. (167° to 176° F.) would kill nearly all the pathogenic germs, and either kill or practically destroy the action of the germs producing milk-decomposition. It would not however destroy the spores; consequently the element of rapid cooling is an important one in the process, in order to prevent the development of these spores later.

The apparatus used by Pasteur was a simple one, consisting merely of a vessel holding wine, the bottom of which was substituted by a receptacle holding water. The water was heated up to 80° or 90° C. (176° to 194° F.) by a fire beneath. When the wine had reached the temperature of 55° C. (131° F.) the process was complete. According to Bitter, Thiel was the first to apply this principle to milk; and after him numbers of pasteurizers have been devised, many of them expensive and elaborate, and intended for the commercial preparation of pasteurized milk. All of them aimed to heat the milk to such a temperature that germs would be rendered harmless and yet the character of the milk remain unaltered. It has been found that a temperature of 80° C. (176° F.) will produce the undesired changes, and even at 70° C. (158° F.) the alteration begins; consequently the temperature employed must be below this. The most important pathogenic germs are killed at a temperature varying from 55° to 70° C. (131° to 167° F.). Probably we are safe in estimating the temperature sufficient for the destruction of the tubercle bacillus to be 68° C. (154° F.), for the typhoid bacillus from 55° to 60° C. (131° to 140° F.), and for the diphtheria bacillus about 58° C. (137° F.). Most of the saprophytes will be killed at a temperature of 65° to 75° C. (149° to 167° F.). It is clear then that if we pasteurize milk at a temperature of 68° to 75° C. (154° to 167° F.) we shall not materially alter its taste and digestibility, but we shall render it practically germless. Bitter and Freeman have each found 68° to 69° C. (154° to 156° F.) the suitable temperature for the purpose. Pasteurization can therefore be recommended as a very satisfactory substitute for sterilization, without the disadvantages of the latter.

I wish, however, to call attention to the following limitations of the process: In using pasteurization we are always on the edge of danger. We are much more liable than with

a temperature of 100° C. to have decomposition of the milk take place later. Milk which has been pasteurized will not keep as long as sterilized milk. We are not comparatively safe, as with sterilization, in leaving the milk in a warm place. It should always be kept cool, and when possible on ice. In the heat of summer, in the case of poor families where one has reason to distrust the ability to keep the milk cool, I should much rather depend upon sterilization, believing that this with all its faults is much safer than using milk not prepared at all, or that which pasteurization has rendered only partially safe—that is, deceptively unsafe. But under any other conditions pasteurization is certainly much to be preferred.

Then I want to utter a warning against the makeshifts for pasteurization which are recommended by some physicians. In this process we are dealing with temperatures which allow of little variation. Consequently to tell a mother—as is often done—to fill the bottles with milk and place them in a dish-pan of boiling water just removed from the stove is in my opinion a very dangerous thing to do. We do not know what temperature is attained in this way, whether too low to be of any value or so high that we are getting all the disadvantages of sterilized milk. It is far safer to scald the milk in the old-fashioned method. Even with so good an instrument as the Arnold sterilizer the accurate pasteurization of milk is a difficult matter. If we leave the hood off of the sterilizer and set the lid ajar, we will find that the temperature varies from 80° to 90° C. (176° to 194° F.)—a temperature entirely too high—depending upon the heat of the fire. And even if we use a thermometer and sit down and watch the pasteurization, it is almost impossible to obtain a uniform temperature in this way. What is needed is some simple apparatus which any nurse-girl can use and which will give accurate results. Such an apparatus is the pasteurizer devised by Dr. R. G. Freeman, of New York. It consists simply of a metal pail, into which fits a receptacle holding the bottles to be sterilized. The receptacle is so made that each bottle fits into a separate small metal cylinder slightly larger than the bottle. In using the apparatus the pail is filled with water to the level of the groove running around it; it is then placed on the stove and the cover put on. The proper amount of milk for each feeding is put into each bottle, the bottles corked with raw cotton and placed in the receptacle. Water is

then poured around them into each cylinder, in order to prevent the direct action of the hot water in the pail from cracking the bottles. As soon as the water in the pail is boiling it is removed from the fire and placed out of the draught upon a non-conducting substance. The lid is now removed, the receptacle put in and the lid reapplied. It is left thus for forty-five minutes, when the lid is removed and the receptacle elevated so that it rests upon supports which hold it partially out of the pail, and a stream of cold water is now turned into the pail for fifteen minutes. The bottles are then kept on ice till needed. The principle of the apparatus is the fact that the given quantity of water which is in the pail will, in cooling, elevate the temperature of the milk to the desired degree; so that the two liquids become of the same temperature at 68° to 69° C. (154° C. to 156° F.). Receptacles are made either for ten six-ounce bottles or seven eight-ounce bottles, and either receptacle will fit into the pail.

Freeman has made thermometric experiments with the apparatus. He finds that in the first five minutes the milk rises to a temperature of 50° to 55° C. (122° to 131° F.); in ten minutes it reaches 60° to 65° C. (140° to 149° F.); and in fifteen minutes has reached 65° to 68° C. (149° to 154° F.). It continues at about 68° to 69° C. (154° to 156° F.) for the remaining thirty minutes, at which time the cold water is turned on; in fifteen minutes from this time the milk has dropped to the temperature of the cold water used. He recommends that when the milk is first received from the milkman it be put in the refrigerator. But he finds that whether the milk be put into the bottles at 10° C. (50° F.) or at 20° C. (68° F.), the approximate temperature of the room, the resultant temperature during pasteurization varies only 2° C. (3.6° F.)—an amount entirely insignificant.

In conclusion I have only heartily to recommend this apparatus to your consideration. I think it will spare you a world of anxiety and prove the saving of a vast amount of trouble to the mothers of your little patients.

I would acknowledge my indebtedness especially to the articles of Bitter (*Zeitschrift für Hygiene*, 1890, viii, 240); Flügge (*Zeitschrift für Hygiene*, 1894, 272); Soxhlet (*Münch. Med. Woch.*, 1886, Nos. 15, 16); Leeds (*American Journal of the Medical Sciences*, June, 1891); Freeman (*New York Medical Record*, 1892, ii, 8; *Archives of Pediatrics*, August, 1896).

## SIMPLICITY AND PALATABILITY IN PRESCRIBING.

BY DR. A. L. BENEDICT,

Professor of Physiology and Lecturer on Digestive Diseases,  
Dental Department, University of Buffalo.

There are a few time-honored medical dicta that are to be found in most text-books and in all orthodox lecture courses, but which are usually promptly forgotten by the student and disregarded by the practitioner, unless he should be called to the chair of a medical teacher. In this category are the theoretical description of temperaments and the therapeutic phrase "*curare tute, cite et jucunde*." Unfortunately, however, this last rule is often so drilled into the mind of the student by successive teachers of materia medica and therapeutics, and is so often found in the "general considerations" of various text-books on this subject, that the physician adheres to it as a practical guide, instead of allowing it to lapse into a harmless theoretical concept. Polypharmacy has its claim to respectability largely on the conception of "basis, adjuvant, corrigent, and vehicle." We have progressed from the old notion that a physician's professional standing was in direct ratio to the number of ingredients in his prescription, and we ridicule as a "shot-gun" prescription one calling for more than half a dozen drugs, unless—like some tonic and cathartic compounds—it is backed by some famous name. We have not, however, attained the moral courage necessary to prescribe one thing for one indication. A prescription calling for only one or two drugs occasions a sense of incompleteness; we pause before signing it, to think if we cannot add something—harmless at any rate—to keep the solitary drug or the pair company. On precisely the same principle some persons, after expressing the full idea which they have in mind, feel that their sentence is too abrupt unless they add "Don't you know," or some similar phrase.

Little as we agree with the symptomatic prescribing of the homeopaths, we must give them credit for originating and, so far as possible, adhering to the rational method of prescribing one drug at a time, and according to a definite system. We may not admire the superficial observations and the reliance on subjective symptoms involved in "proving" a drug, but we must respect the genuine homeopath for giving bryonia, with a definite idea and a firm faith, not because he has heard that it was "good for" a certain dis-

ease or because "he didn't know just what else to give."

Just as the charlatanism of phrenology was an effort—though perhaps not an honest one—in the same direction in which cerebral localization has recently made so much progress, so Hahnemann's system of drug-proving was an attempt—and, personally, I believe a conscientious and painstaking one—at solving the problems which pharmacology and physiological chemistry are now attacking on a rational and scientific basis. The ideal prescription is an equation between a definite understanding of pathology and an equally definite information as to the action of drugs. Unfortunately, the equation is not always possible; we are still ignorant of the true nature of many diseases; we are not infrequently confronted with practically insoluble problems in diagnosis; and there are many drugs which act, we know not how. The prescriber should, at least to himself, be keenly critical of his prescription and should know why he advises every ingredient, even if he has to confess at times that ignorance has forced him to empiricism.

In a very different sense from the accepted one, the ideas of basis, adjuvant and corrigent must still be borne in mind. Seldom does a disease depend upon a single pathological change so that it can be combated by a single remedy, and we may properly concentrate our attention on one indication as of prime importance. But even in these circumstances we must set each drug against its own indication and afterward consider whether harm will arise from administering all the bases, and which, if any, are to yield to the superior claims of others. But the conception here is quite different from that in which the prescription is a unity, with one drug supported by and modified by others. For example, in many cases of dyspepsia there is need of hydrochloric acid, of strychnine, and of iron. But who can say that among these aids to secretion, to motion and secretion, and to general nutrition, respectively, one is a basis, another an adjuvant, and the third the corrigent? We shall be very likely to regard the indication for iron as offset by the inability of the weakened organs to assimilate it, but the indication remains as urgent as before. Neither is it wise to combine the other two remedies, first, because the sour and bitter mixture will be very apt to excite vomiting; secondly, because the strychnine will act most efficiently on the empty stomach, while the acid

is most needed toward the height of digestion. Again, in many cases of bronchopneumonia the indications are very clearly (1) to liquefy secretion; (2) to strengthen the heart; (3) to disinfect the air passages and favor resolution. To render the problem simpler, let us ignore the more modern and perhaps superior action of sprays and confine our attention to medicines administered by the stomach. Ammonium chloride, digitalis, and eucalyptol may be taken, respectively, as examples of the corresponding drugs, though various circumstances, including individual prejudices, may lead to the selection of substitutes for each or all. It is unwise to mix these drugs in one prescription, under the conception of basis, adjuvant, and corrigent. Such a mixture is physically incompatible, is extremely nauseating, and by upsetting the stomach is apt to nullify the desired cardiac stimulation. Ammonium chloride dissolved alone in water has merely a pungent, salty taste which is readily removed by a sip of plain, cold water. The digitalis, if given in tablet form, will scarcely irritate the most sensitive stomach, while the eucalyptol, or other volatile principle, is least disagreeable when taken in temporary emulsion with water or milk, followed by coffee or other drink to remove the taste. Again, the ratio between the various medicines should be a changeable one. For the first day, more liberal doses of ammonium chloride will be necessary than later; digitalis will usually have to be discontinued, or at least reduced, after four or five days; various unforeseen occurrences in the course of the disease may call for the increase or diminution of the dose of any one drug. This argument applies also to most cases in which indications for several different medicines coexist. Whether we consider economy, convenience, or palatability, it is usually better to order each medicine by itself.

The conception of corrigent is, unfortunately, a necessary one, simply because so many of our standard drugs have associated actions, some one of which may prove injurious. As we rely more on alkaloids and synthetic compounds and less on crude drugs, the less important will the problem of corrigents become. The matter of "crossed action" depends on the same difficulty of obtaining a drug whose action is simple and uncomplicated, with untoward tendencies. Sometimes the administration of a number of drugs means that we do not dare to give any one in a sufficient dose to overcome the

symptoms presented—not that a true crossed action is desired. Thus, in delirium tremens, we cannot safely give morphine according to its effect, but we may give as much as we dare of this alkaloid, follow it with hyoscine to the therapeutic limit, give a dose of bromide—not perhaps as large as would be compatible with safety, but so large that further increase would not be attended by increased physiological effect—add a moderate dose of acetanilid and of cannabis indica,—all without producing the desired result, so that we may be forced to chloroform anesthesia. In internal hemorrhage, we have the indication for some drug that will constrict blood-vessels, without similarly adding to the tone of the heart. Ergot probably fulfils this indication as well as any drug; but none is perfect. Thus the problem is clearly presented of effecting a crossed action by reducing the cardiac tone by a drug that will not lower vascular tone. Here again the therapeutic problem is unfulfilled—at least so far as the writer knows. The use of strychnine before or during anesthesia, the well meant but improper combination of nitrite of amyl with chloroform, the addition of carminatives to cathartics, are all illustrations of corrigent medication which is but a confession of the imperfections of our materia medica.

Regarding vehicles, very false ideas are current. Too many physicians, even among those who write for publication, foster the impression that a disagreeable drug can be “elegantly” given by adding a syrup and either a fruity or an aromatic flavor. This is comparatively seldom the case. Some persons are fond of peppermint or wintergreen, others of the various spices, others of rose, orange, lemon, etc. But any one of these flavors may be exceedingly disagreeable to a particular individual. Oil of wintergreen is often recommended as a salicylate—containing a high percentage of methyl salicylate—but the writer has found that most persons, even including those who express themselves as liking wintergreen, soon tire of the strong flavor and prefer the sodium salt. Strongly saline, bitter and oily drugs should almost never be given with a syrup. Salines are most easily taken well diluted and followed by a drink of plain water, which will remove the taste almost entirely. Bitter medicines, like strychnine and quinine, can usually be quickly swallowed in capsule, pill or tablet form, without offending the palate. Unless the sense of taste can be temporarily obtunded by a little cocaine, a strong volatile oil, or

even a pinch of salt, many patients will prefer to take a disgusting medicine by itself, removing the taste by afterward drinking some strongly flavored beverage, such as coffee, rather than to mix a bitter and a sweet taste or to spoil by the medicine the flavor of something of which they are fond. Few physicians would use gravy into which the cook had put sugar instead of salt, but many will prescribe cod-liver oil “with a pleasant syrup to disguise the taste.” There are a few palatable emulsions of cod-liver oil, but most of them will cause unpleasant regurgitations; and far more agreeable and less irritating to the stomach are the almost pure and tasteless oils which may be salted and taken clear or on bread. However, the writer holds the heretical view that crisp salt pork, cream, fresh butter, salad oil, fat meats, etc., are superior to cod-liver oil.

Iron and other heavy metals, as well as arsenic, may well be given in syrup. Two of the most palatable syrups are almost unused, that of raspberry and, best of all for the majority who like it, chocolate. The last, in spite of its superiority to all other vehicles—excepting that those who are not especially fond of it usually dislike it very much—is not even official. It is by all odds the best disguise for quinine, and it will nearly conceal other bitters and astringent mineral salts. It is also available for tablets and confections. A few syrups, like that of squill, are actively medicinal. This is to be regretted, as it ought to be possible to give all syrups *ad libitum*.

To sum up, the writer would advocate (1) the use of drugs according to known physiological actions, except when scientific ignorance and clinical experience render empiricism necessary and proper; (2) the use of one medicine at a time, unless coexisting pathological processes demand more; (3) the prescribing of medicines separately, unless it is reasonably certain that their conjoined administration will be safe and agreeable and that their relative doses will remain stationary; (4) the administration of disagreeable medicines in solid form, so that they may be swallowed untasted, unless physiological activity will be sacrificed; (5) the application of common-sense rules according to habits of eating and drinking, in administering medicines whose taste cannot be avoided by insolubility in the mouth. This last means that we shall not mix bitter and sweet things unless the bitter can be almost completely covered; that we shall transform acids into

lemon- or orange-ades or into "shrub" drinks; that we shall salt oily substances and not sweeten salty ones; that we shall respect idiosyncrasies; that when a taste cannot be covered, we shall not try to mix it, but shall rely on rinsing the mouth or establishing a pleasant after-taste.

*TREATMENT OF CANCER OF THE RECTUM, WITH A REPORT OF TWENTY-FIVE CASES.\**

BY W. W. KEEN, M.D., LL.D.,

Professor of the Principles of Surgery and of Clinical Surgery,  
Jefferson Medical College, Philadelphia, Pa.

[Concluded.]

*CASE I.—Resection of four inches of the rectum from a point two inches above the anus, by Kraske's method; recovery; gain in weight, about fifty pounds in nine months. Second operation thirteen months later to re-establish the continuity of the rectum; death from infective peritonitis.*

Rev. W. W. F., of Pottsville, Pa., aged sixty-one, five feet five inches, weight 168 pounds, first consulted me November 16, 1891. He had lost fifteen pounds in the last eighteen months. For two years and a half he had had trouble in his rectum, with frequent bloody stools; sometimes his stools were watery without blood. Of late there had been an almost constant desire to evacuate the bowels; occasionally the call was so urgent that he had been unable to reach a convenient place before having the evacuation. His sleep also was disturbed by it. He had moderate pain and a great sense of rectal fulness all the time. His rectum had never been examined by his physician. Rectal touch revealed a large tumor, especially marked on the anterior wall of the rectum, beginning three inches above the anus. For a week before the operation the bowels were persistently evacuated, partly by enemata, partly by laxatives, both of which were administered daily, and it seemed as though the bowel had been completely emptied.

Operation December 2, 1891. By a curved incision from the posterior inferior spine of the ilium to just posterior to the anus the bones were exposed, the rectum separated, and the coccyx and the sacrum removed at the level of the third sacral foramina. Separation from the prostate and the bladder was very easy, excepting at the level of the

diseased mass, where the adhesions were quite intimate, and in loosening them the peritoneum was opened purposely and quite widely; the bowel was brought down with difficulty owing apparently to the two inferior mesenteric arteries, which acted like guy-ropes. One enlarged gland was found in the meso-rectum. During the dissection the weakened bowel gave way at several points and allowed the contents of the rectum to escape. Sponges, however, were placed in the peritoneal opening and prevented contamination. The opening in the peritoneum was not closed by suture. The diseased portion of the bowel, beginning at a point six inches above the anus and terminating at a point two inches above the anus, was resected, and the cut upper end fastened to the soft parts at the end of the resected sacrum. A long rectal tube was carried up into the colon, and the bowel was then washed out continuously for at least ten or fifteen minutes. In spite of the preliminary cleansing, the amount of material seemed to be endless. I feared to prolong the operation, which had already lasted about two hours, and so desisted from washing out the bowel before it was entirely clean. The long time consumed was probably on account of its being my first resection of the rectum by Kraske's method, and I was therefore unfamiliar with its technique. The patient stood the operation very well. The amount of blood lost was only moderate. Three drainage tubes, one on each side and one posteriorly, were used. He made a slow but satisfactory recovery, the wound filling up by granulation and closing in a month. When he got out of bed his weight was 147 pounds; three months later it had risen to 185 pounds, the heaviest weight he had ever attained, and he felt as well as he ever did in his life. By September, 1892, nine months after the operation, his weight had reached 192 pounds. No incontinence of feces existed during the night, but in the daytime he had no satisfactory control. In addition to this there was such prolapse of the bowel, often amounting to six or seven inches, that he desired if possible to have the continuity of the bowel restored.

Second operation January 19, 1893. On inserting a finger of one hand into the natural anus and a finger of the other into the artificial anus, I found that there was less than a quarter of an inch, apparently, between the two fingers. I therefore attempted to use Murphy's anastomosis button at this point by cutting a small opening with scissors, but the

\* Read before the West Branch Medical Association, at Bellefonte, Pa., Jan. 12, 1897.

shank of the button was too short to allow of the penetration of the shank sufficiently to attach the two halves. Accordingly, after a somewhat persistent trial, I was obliged to abandon this method of anastomosis. I had carefully examined, as had also my colleagues, Professors Montgomery and Hearn, to see whether the peritoneal cavity was invaded by the opening just made. There being no evidence of its involvement, I drew a rope of iodoform gauze through the opening so as to keep it patent, with the intention of closing the artificial anus when the anastomosis was perfect. For two days everything went well, but on the third day his temperature rose to  $101.2^{\circ}$ , the following day to  $103.2^{\circ}$ . On the second day the iodoform gauze packing was removed and the bowel thoroughly douched with warm boiled water. There was no tenderness over the abdomen and no other symptom to indicate peritonitis until the third day, when there was very slight abdominal tenderness. His strength, however, failed rapidly and he passed into unconsciousness, dying on the fifth day. No discharge of pus had occurred from either the anal or the upper portion of the bowel.

The post-mortem showed adhesions of the coils of intestine and of the pelvic organs throughout the pelvis, and considerable pus from the site of operation upward into the sac of an old indirect inguinal hernia.

*CASE II.—Resection of six inches of the rectum by Kraskie's method to a point eight inches above the anus, preceded by an inguinal colostomy (Maydl's method). Eight days required to cleanse the bowel after the colostomy. Recovery. No recurrence for four years and two months. Social and business life unhampered; good control of feces. Rides a bicycle.*

Mr. B., Philadelphia, aged thirty-two, was first seen on June 10, 1892, in consultation with Dr. Wharton Sinkler and Dr. James C. Wilson. Weight in April, 1892, 175 pounds; best weight, 185 pounds. In 1876, when out camping, he lifted a heavy log, following which he had a hemorrhage from the bowels amounting to several ounces, but has had none since. No other ill effects followed, nor was he aware of anything having given way. His appetite had always been abnormally great and he indulged it without wise restraint, both as to the amount and character of his food. He had also been remarkably constipated. In the autumn of 1891 he noticed that there was considerable mucus in his stools. In December, 1891, he had an attack of grippe, for which, in January, 1892,

he went to Asheville, N. C. While there he had a severe attack of pain in the hypogastrium with diarrhea, and from that time on not only was there mucus but blood was observed almost daily, never however amounting to a hemorrhage. On May 30, 1892, he had such a violent attack of obstruction that his life was endangered, but it finally yielded to treatment. Another slight attack followed soon after. Hemorrhoids were also present and were very painful and tender, so that when I saw him it was not possible to introduce the finger to any considerable extent into the bowel, and I was unable to examine the rectum thoroughly. On July 16 he was etherized and three hemorrhoids were removed by the Paquelin cautery. I took advantage during this etherization to examine the rectum higher up. The moment that the sphincter was dilated a ring of teat-like processes appeared scattered over the rectum and merged at a higher level into a mass which there was no doubt was a carcinoma. Two of these processes were twisted off and were examined by Prof. W. M. L. Coplin. He reported that while the general structure of the specimen was that of an adenoma of the rectum, yet it pointed to a rapid degenerative process and for all practical purposes, therefore, was to be considered a tubular epithelioma. As the weather was very hot and he had lost much strength in consequence of it, we did not deem it wise to make a radical operation at this time. He was therefore given a bland, liquid, nutritious diet, and later a solid diet as his stomach would assimilate it, the bowels kept loose with laxatives, and as soon as he was able he was encouraged to get up and walk out of doors.

Early in August he went to the seashore, and returned early in October weighing 168 pounds, a gain of 23 pounds in ten weeks. On October 22 he was etherized for the purpose of a thorough examination, which was participated in by Drs. Sinkler, Wilson, Robert F. Weir of New York, and Robert W. Johnson of Baltimore, as well as myself. It was found that the tumor had grown considerably in size, but was still movable and not attached to the bladder anteriorly. It was situated about four inches above the anus. The finger was passed through the lumen of the growth with difficulty, therefore it was not certain that we could reach the upper border of it.

Operation November 5, 1892. A Maydl operation was done in the left inguinal region

on this date. The sigmoid flexure had a very short mesentery. Five hours after the operation he complained of pain due to the retention of flatus from a too acute kink over the glass bar. On attempting to pull down the upper part of the colon I found that it was very adherent, so that it required considerable force to loosen it. Three days afterward the sigmoid was opened by scissors, the bar being left in place till the end of a week. For eight days after this the lower bowel was washed out every day, both from the artificial anus and the natural anus. After the first two days the return liquid was entirely clear, yet on the fifth day a large movement occurred from the natural anus, showing that considerable fecal matter still blocked up the rectum below the artificial anus. Fifteen grains of ox gall were then thrown into the lower rectum from above, which broke up and dislodged considerable fecal matter.

Operation November 16, 1892. Ether; duration of operation, two hours. Four and a half inches of the coccyx and sacrum were removed, going up to the third sacral foramen. The lower end of the spinal canal was opened and a small amount of cerebro-spinal fluid escaped. A catheter was held in the bladder to define the limits both of the bladder and of the urethra. The peritoneum was opened, as it was impossible to draw down the bowel without doing so, but was immediately fastened to the wall of the rectum by a continuous silk suture. The rectum was divided two inches above the anus and again at a point eight inches above the anus. The stump of the rectum was then attached to the end of the sacrum, two large drainage tubes were inserted, one on each side, and the anterior wound was packed with iodoform gauze. I did not suture the two ends of the bowel together—though mechanically this would have been possible—because the operation had already lasted two hours, his condition was not very good, and independent of this I was not much in favor of such anastomosis. He made a slow but sure recovery, the wound closing entirely at the end of about six weeks. The tumor was examined again by Professor Coplin and pronounced to be a tubular epithelioma.

Four years and two months have elapsed since the date of the operation. The patient has been in such good health that his weight has exceeded 200 pounds. He was abroad for over two years, traveling in various parts of Europe along the Mediterranean, in Egypt, etc., and entering freely into all

his ordinary social relations. His latest achievement has been to ride a bicycle (with a Christy and not a perineal leather saddle); which he has done without any trouble. The inguinal anus has been so comfortable that he has not cared to have any attempt made to re-establish the continuity of the bowel and close the inguinal anus.

His mode of dressing the openings is as follows: First, the sacral anus: as some mucus escapes from this he applies two squares of absorbent cotton and over that a sheet of wood-wool, retaining them in place by a T-bandage. Secondly, the inguinal anus: three pads of absorbent cotton to the right, left, and below the opening, then another pad over the whole, then rubber dam, another layer of cotton, and a binder.

At times the bowel protrudes from the sacral anus from two to six inches, but he has no difficulty in replacing it. His control over his movements is good. What is curious, in view of the absolute severance of the bowel at the inguinal anus into an upper and lower part, is that about every two weeks a very small but positive fecal movement occurs from the sacral anus; evidently a small amount of the feces, which escapes from the upper colon at the inguinal anus, is forced back by the pads into the lower opening of the colon and finally escapes, as stated, through the sacral anus.

CASE III.—*Amputation of nine and a half inches of the rectum by Kraske's method, preceded by an inguinal colostomy (Maydl's method). Recovery. No recurrence after four years. Excellent control over evacuations. Social and business life unhindered. Can ride a bicycle.*

Mr. F. was kindly brought to me by Dr. H. W. Elmer, of Bridgeton, N. J., on December 14, 1892. Aged forty-six; best weight 185 pounds, present weight 152 pounds. Two years before he noticed a fissure of the anus, which was followed by hemorrhage and constant discharge. On examination I found a distinct ulcer on the left side of the anus about one inch in diameter and extending upward. From that a very widely spread carcinomatous growth extended at least three to four inches up the bowel. He also had a left oblique inguinal hernia.

Operation January 6, 1893. I did a Maydl operation in the left inguinal region, and two days later opened the bowel with the Paquelin cautery, dividing it completely in two down to the bar. I then systematically washed out the rectum and colon both from the artificial and the natural anus.

Operation January 18, 1893. Kraske's operation was done, the incision passing from the left antero-posterior spine to a point an inch in front of the anus and encircling that opening. A bougie was inserted into the bladder, and when I separated the rectum in front I found I had laid bare and recognized in the various steps of the operation the bulbous portion of the corpus spongiosum, the membranous urethra, the prostate gland, and a considerable portion of the wall of the bladder. The peritoneum was opened, but sutured soon afterwards to the anterior and lateral walls of the rectum. No enlarged glands were found. Nine and a half inches of the bowel were removed and the stump of the rectum attached to the end of the sacrum. A drainage tube posteriorly and iodoform gauze anteriorly were placed. No rise of temperature followed the first operation. After the second operation the temperature rose from the second to the fifth day to as high as  $102.4^{\circ}$ , but reached the normal on the ninth day. The stitches were all removed at the end of eight days. On the fifteenth day he sat up, and at the end of the fifth week went home. No irritation of the bladder followed.

Dr. D. Braden Kyle examined the specimen and reported that it was an epithelioma.

Present condition, December, 1896, after four years: A very moderate prolapse of the bowel takes place, especially in the summer-time. When that occurs he is obliged to stop and rest. I saw him December 21, 1896, within a month of four years after the operation. His weight is 185 pounds. He is in vigorous, robust health, and has been ever since the operation. He is one of the most active business men that I know. He comes frequently to the city in the morning in order to make purchases for his several stores, and returns in the evening after a hard day's work. Ordinarily he has two voluntary movements, one at night and one in the morning. If his bowels are loose he is obliged to give very careful attention to himself, and sometimes is unable to attend to business satisfactorily. This is rarely the case, and commonly one would never know that there was anything abnormal in his person or his history. He usually defecates standing. His observations in regard to the flow of mucus from the sacral anus and his method of dressing the wound, with which he has had a good deal of experience and in which he has shown a good deal of ingenuity, are as follows:

"The amount of mucus depends altogether

upon the amount of irritation, and that generally upon overexertion or temporary ill health. It is a wonderfully sympathetic part of my anatomy and is always affected by a bad cold with any accompanying coughing and sneezing, even the dynamic of nose-blowing finding a resultant there. Riding in a wagon on a rough road hurts it very much. I have tried the bicycle, but have not yet learned to ride it. I have succeeded in so arranging the pad of my bandage that all flow of mucus is absorbed, one pad lasting if necessary for twenty-four hours. The inguinal anus gives me no trouble beyond the necessary inconvenience attending the discharge of fecal matter, and that has been reduced to a minimum. Occasions of being caught so that I am obliged to run to cover are very few and far between, and it is getting to be the rule that I require no attention between rising and retiring.

"I dress the anus as follows: a thin layer of antiseptic wool, another of absorbent cotton about the size of a sheet of paper (six by ten inches), a piece of muslin of the same size, then another layer of cotton still larger, another of muslin, then a sheet of rubber dam and a bandage of heavy unbleached muslin is an absolute defense against any happening excepting genuine diarrhea, and that has to be very bad to get away with me. If a movement occurs that is formed and I can attend to it soon, frequently only the first or second layer needs to be discarded. At night there is frequently very little mucus. My truss is a powerful safety guard, holding the lower edge of the bandage tightly to my body, preventing the escape even of very thin fecal matter, and I do not see how I could get along without it even if there were no hernia. My eating habits are methodical. I make it a rule to eat stewed or raw fruit for supper and drink somewhat freely. A cup of strong coffee on getting out of bed in the morning or before brings everything down and out in good shape within an hour, and then I dress and go about my business with serene confidence."

(This observation as to the truss would suggest that in such cases a dummy truss might be used to advantage.)

His method of dressing the sacral anus is ingenious and might prove useful to others. With a view both to absorbing the mucus and preventing the prolapse of the bowel he uses an ordinary metal shoe-horn, the convex surface turned next to the skin and narrow end forward, and covered as follows: a piece of

canton flannel four by six is folded lengthwise, the corners turned, and the shoe-horn slipped in between the two folds and fastened by safety-pins; a second layer of canton flannel, then a double layer of absorbent cotton slightly wider than the flannel, and a layer of globe antiseptic wool about an inch wider than the absorbent cotton. To prevent chafing, some aristol is spread on the surface of the sterilized wool. All of these layers of cotton, wool and flannel go between the shoe-horn and the skin; the whole is then kept in place by the T-bandage already mentioned.

CASE IV.—*Five inches of rectum amputated by Kraske's method, preceded by an inguinal colostomy (Maydl's method). No return after four years. General condition satisfactory.*

Geo. M. R., aged fifty, was admitted to St. Agnès' Hospital November 15, 1892, at the instance of Dr. John J. Black of New Castle, Del. I publish the case by the kind permission of Dr. A. W. Ransley, with whom I was associated in its management. He had had dysenteric symptoms for four months. An extensive, very soft, bleeding carcinoma of the rectum was found by touch. Operation December 3, 1892. An inguinal colostomy was done by Maydl's method. The bowel was opened on the second day. Second operation December 15, 1892. Amputation of the rectum was done, the sacrum being divided transversely between the second and third sacral foramina. About five inches of the bowel were amputated, and the upper end sutured to the end of the resected spine.

Present condition: There is no indication of a return of the disease after four years. The inguinal anus does not annoy him seriously, but he is somewhat reluctant to go into society. He has on an average two movements a day, morning and evening; has no control over them, but is aware of them before they pass. There is a moderate protrusion of the bowel at the inguinal anus, two and half inches, and about three inches from the sacral anus. He is not annoyed by the amount of mucus discharged from the bowel. His general health is first-rate.

Dr. John J. Black, who kindly sent him to me at the hospital, says that "to-day he would pass for a man hale and hearty, forty years of age; eats everything, and plenty of it. No irritation from abrasions of the skin."

CASE V.—*Amputation of six and a half inches of the rectum by Kraske's method, preceded by inguinal colostomy (Maydl's method);*

*bowel not fully cleansed after seventeen days' constant washing; spinal canal opened. Recovery.*

Joseph A., aged forty-six, Altoona, Pa., entered the Jefferson Hospital October 13, 1893. His family history is good. Up to January, 1893, he had always been well, but at that time he noticed a slight amount of blood in the stools. This continued almost all the time up to his admission to the hospital. Constipation of late had been very marked; the fecal masses were diminished in diameter until they had become ribbon-like. He had very little pain, but great discomfort in the rectum; no vomiting; loss in weight fifteen pounds. On examination I found a rather slender man with a moderately cachectic look. Specific gravity of urine 1.023, no albumen, a slight trace of sugar. By rectal touch, an inch above the anus, a hard irregular mass was immediately encountered; the fingers could not be passed through it. I found also some hemorrhoids. By abdominal examination the descending colon and sigmoid flexure showed a row of irregular lumps, whether hardened feces or extension upwards of the disease I was uncertain. I advised an exploratory operation in the left iliac region to determine, first, the nature of these masses, as a differentiation between scybala and cancer could not be made by means of high injections on account of the obstruction by the disease; secondly, if they were found to be scybala, that a Maydl operation should be done immediately and the extent and character of the rectal growth be determined; thirdly, if they were found to be nodules of disease, that a right colostomy be done. Left inguinal colostomy by Maydl's method was done October 15, 1893. The hardened masses were found to be scybala. The bowel was opened twenty-four hours after the operation by a longitudinal incision by the Paquelin cautery. The bar was removed at the end of a week. From October 16, when the bowel was opened, to November 2, a period of seventeen days, the bowel was washed out both upwards and downwards toward the stomach and toward the rectum by copious enemata, sometimes of warm water and sometimes of ox gall, with the intention of absolutely cleaning out the bowel. Injections were also made from the anus, but very small amounts of fluid could be passed in in this way. I appointed the Kraske operation for the 28th of October, twelve days after the opening of the artificial anus, but on that morning, in spite of all the washing out already done, he was taken with diarrhea, during which an

immense quantity of feces poured out of the artificial anus, the oozing being almost continuous for about sixteen hours. The fecal torrent having then been arrested and the bowel apparently clean, I did the Kraske operation on November 2, 1893. The coccyx and two and a quarter inches of the sacrum were removed; the prostate and part of the bladder were uncovered in the dissection. I attempted to remove the diseased portion without opening the peritoneum, but found it impossible to get above the upper edge of the disease. Accordingly the peritoneum was opened, the rectum drawn down, and the peritoneum immediately sutured to the anterior wall of the rectum, thus closing the cavity. In order to obtain access to the rectum I found it necessary to remove three-quarters of an inch more of the sacrum, making three inches in all of the sacrum and coccyx. The spinal canal was opened by the removal of this portion of bone. When doing this, at the left edge of the coccyx I discovered a considerable area of the bone so softened that the finger-nail could easily break it down. All of this left side up to the border of the great sacro-sciatic foramen was then removed by forceps and gouge. No enlarged glands were found in the meso-rectum. The anal portion of the bowel which was normal was so small that I removed this as well as the diseased part. The portion removed measured six and a half inches. The stump of the rectum was attached at the end of the resected spine.

The hemorrhage was only moderate. Iodoform gauze was packed posteriorly and anteriorly to the rectum. The operation lasted an hour and three-quarters and the patient showed marked shock, but reacted very well. To my surprise, on the second day after the operation, in spite of all the washing out begun nineteen days before, a very large amount of fecal matter was discovered impacted in the rectum and had to be removed mechanically, after which a considerable amount was spontaneously evacuated during this and the next day. On the sixteenth day the patient sat up, and on the twenty-fifth day left for his home. His highest temperature was 102°, and the normal was reached at the end of a week. Except where the gauze drains were placed, absolute union by first intention took place. No later history has been obtainable.

CASE VI.—*Cancer of the rectum, anus, and vagina. Amputation of six inches of the rectum by Kraske's method with a V-shaped piece of the recto-vaginal septum, preceded by an inguinal*

*colostomy by Maydl's method. Death in thirteen hours from shock.*

Mrs. P. M. was first seen June 10, 1893. Aged thirty; married five years, three children. Before her marriage she suffered from prolapse and retroversion of the uterus and moderate prolapse of the bowel. Two years and a half previous to my seeing her she noticed a very slight pinkish discharge from the rectum, but had no pain in defecation until sixteen months subsequently. Since that time the pain had gradually increased until it became excessively severe, keeping her in misery for a number of hours after each movement. During this same time the fecal masses had diminished in diameter until they became the size of the little finger. In December, 1892, a small portion of the growth was removed by another surgeon. The growth was at that time thought to be benign, but the microscopical examination showed it to be malignant. I etherized her in order to make a careful examination. Nothing abnormal was found in the abdomen. At the anus there was an ulcerated mass entirely surrounding the orifice, with outgrowths of an inch or more in length. The introduction of the finger showed a hard nodular growth surrounding the rectum. By some pressure the finger could be forced through the growth and detect its upper limit. The recto-vaginal wall was partly involved on its rectal aspect up to the junction of the vagina and uterus, but the mucous membrane was not involved, excepting just at and above the anus.

June 17, 1893, Maydl's operation was done. There was some difficulty in finding the colon, which was displaced far to the right. The colon was stitched at each end of the incision. The bowel was opened three days later by the Paquelin cautery, dividing it completely to the bar.

June 28. After having daily washed out the lower bowel through the artificial anus with ox gall, boiled water, boric acid, etc., a Kraske amputation of the bowel was done. In separating the soft parts from the sacrum and coccyx posteriorly I was struck with the advisability of not going too close to the bone, so that the vessels which bled freely could be caught much more easily than when they were severed very close to the sacrum.

The sacrum was resected at the level of the third sacral foramen. No enlarged glands were felt in the meso-rectum. The rectum was dissected loose chiefly by the finger, the levator ani being divided by knife and scissors. The incision was then carried around

the anus and sufficiently far into the vagina to include a generous healthy portion, as well as the diseased portion of the septum. With one finger in the vagina it was easy to ascertain the limits and relations of the diseased portion to the rectum, and a V-shaped piece was removed, its apex reaching nearly up to the uterus. The peritoneal cavity was opened, the rectum drawn down, and the peritoneum then stitched to the anterior and lateral borders of the rectum. Six inches of the rectum were amputated. The posterior wall of the vagina was now united by a continuous Lembert suture, approximating the raw outer surfaces of the vaginal wall on each side. Drainage tubes were placed at the anterior and posterior extremities of the wound, which otherwise was closed. The operation lasted nearly an hour and three-quarters. The patient was in marked shock. Before the operation she had had  $\frac{1}{4}$  grain of morphine and  $\frac{1}{16}$  grain of strychnine, and  $\frac{1}{16}$  were administered during the operation. During the night the same medication was continued as needed, together with stimulants and external heat. Her temperature barely rose to  $100^{\circ}$ , but her pulse never became perceptible, and she died suddenly at 3 A.M. apparently from heart clot, thirteen hours after completion of operation.

**CASE VII.**—*Cancer of rectum. Five inches of the rectum removed from four to nine inches above the anus by Kraske's operation without prior colostomy. Death after fifty-six hours from uremia.*

Samuel S., aged forty-one, was sent to the Jefferson Hospital by Dr. Stahren March 12, 1896. Family history excellent. He was a moderate drinker; denied syphilis. A year previous he observed a burning sensation in the rectum during defecation. This increased in severity till it became quite painful. After a considerable time he began to pass bloody stools, lost his appetite, and not infrequently had nausea and vomiting. The bowels alternated between constipation and diarrhea. He had lost about ten pounds in weight. On admission his temperature was  $97.6^{\circ}$ ; pulse 98, full and of high tension. The arterial coats were markedly thickened; aortic sounds slightly accentuated. Urine 1.022, no albumen or sugar; urea 2.2 per cent. About three inches above the anus an indurated ulcerated tumor was felt involving the entire circumference of the rectum and constricting it.

Operation March 18, 1896. Owing to his diseased arteries I hastened the operation as much as was possible, and finished it in an hour and a quarter. Four and a half inches

of the coccyx and sacrum were resected to the level of the third sacral foramen. The rectum was separated from the adjacent parts without difficulty. The disease began about four inches above the anus, and the part resected was five inches long. No glands were felt in the meso-rectum. The peritoneum was opened and immediately fastened to the peritoneal surface of the rectum. The stump of the rectum was then fastened at the end of the resected sacrum. The wound became smeared from the fecal matter which was discharged from above the disease, but great care was taken to prevent infection by packing one part of the wound with iodoform gauze while working at another part, and by careful washing with bichloride of mercury afterward. Only about a dozen ligatures were needed. An iodoform gauze drain was passed through the anal segment and the anus, another behind the normal anus, and a third was pushed up into the bowel so as to prevent any fecal infection. It was not possible to approximate the two ends so as to restore the continuity of the bowel. During the night after the operation the temperature rose to  $100^{\circ}$  and he became delirious, with also a very marked diminution in the amount of urine. In the first twenty-four hours after the operation he only secreted  $13\frac{1}{2}$  ounces of urine; in the second twenty-four hours only  $3\frac{1}{2}$  ounces; and in the next eight hours, at the end of which time he died, no urine whatever was secreted. By an unfortunate misunderstanding the urine was not examined. Every means were taken to increase the action of the kidneys, but he died from uremia in spite of them. Dr. Kyle reported that the specimen showed the growth to be a tubular epithelioma.

**CASE VIII.**—*Amputation of two and a half inches of the rectum by the perineal route, with removal of the coccyx (Kocher's method), but no prior colostomy. Artificial sphincter attempted by Gersuny's method followed by infection. Recovery.*

Mrs. B., Vinemont, Pa., aged forty, was admitted to the Jefferson Hospital February 13, 1894. Her mother died of tubercular laryngitis. There is no family history of cancer. For two years she had a sense of rectal bearing down and tension, and occasionally passed blood by the bowel. The pain in the rectum was more severe after exercise. The bowel movements were obstructed. She had no nausea or vomiting, but had lost weight till she now weighed only 103 pounds. Urine normal.

On examining the rectum I found a very distinct nodular growth which began at the anus, but extended only an inch above it. I therefore did no preliminary colostomy, but on February 16, 1894, proceeded to the amputation of two and a half inches of the bowel. The coccyx was removed and the rectum rapidly detached both from the bones behind and the vagina in front. One enlarged gland was found in the post-rectal space. The peritoneum was exposed, but not opened. In this case, in order to obtain an artificial sphincter, I adopted the method of Gersuny, twisting the bowel 270 degrees until there was considerable resistance to the introduction of my finger. It was then sutured to the surrounding skin. Two days after the operation her temperature rose to 102°; the packing which had been put at the anterior extremity of the wound was removed, and I found that feces had escaped in the intervals between the stitches and infected the wound. One stitch was cut to allow of more efficient drainage and the parts then washed out carefully. After this she made a very good recovery and went home March 8, 1894. Dr. D. Braden Kyle reported that it was an epithelioma. I have written to her since then, but have received no reply.

CASE IX.—*Amputation of three inches of the rectum by Kocher's method. Recovery.*

M. D. K. entered the Jefferson Hospital February 14, 1893. Up to 1878 he had been in good health. He was an enlisted soldier at that time and much exposed to the weather, and suffered much from diarrhea and hemorrhoids. The latter were operated on in the post hospital October, 1878, and several times since then. He, however, was never free from the hemorrhoidal trouble, and finally was discharged from the service in 1891. In March, 1892, the hemorrhoids were again operated on, but he has never been well since. He suffered from a constant burning pain in the rectum, and passed at times small amounts of clotted blood. Defecation was very painful; there was no trouble with the urinary organs. On examination a considerable ulcerated surface was seen and felt surrounding the anus, with a mass of infiltrated and hard nodular tissue extending two inches up the rectum. The slightest manipulation caused bleeding.

Operation March 1, 1893. Three inches of the rectum were amputated and the stump attached to the skin of the perineum. The coccyx was removed to give access to the mass, but none of the sacrum. The peri-

toneal cavity was not opened. The wound healed by first intention, the stitches being removed in a week. The highest temperature was 102°. Three weeks after the operation he went home entirely well. No later history has been obtainable.

CASE X.—*Amputation of four inches of the rectum by the perineal route without prior colostomy. Recovery.*

Mrs. X. The notes of this case are unfortunately lost, and I can only give a meagre outline. The case was one of carcinoma of the rectum involving the anus, which I operated on in the Jefferson Hospital in 1890. About four inches of the rectum were resected without removing the coccyx or opening the peritoneum. The patient made a prompt recovery. Of her condition since then I have been unable to learn anything.

CASE XI.—*Amputation of three inches of the rectum by the perineal route; recovery. General health and business activity entirely restored. No return in four years, when he died from an acute diarrhea.*

Mr. McK., aged fifty-four, was seen in consultation with Dr. H. G. Hill February 1, 1891. Prior to seeing Dr. Hill he had thought he had hemorrhoids for some years. On examination Dr. Hill immediately detected the growth—epithelioma of the anus and rectum for two and a half inches.

Operation February 6, 1891. Three inches of the lower end of the bowel were amputated, the peritoneum not being opened. No bone was removed. A sound in the bladder was useful as a guide. The end of the bowel was sutured to the skin, a drainage tube being introduced on each side of the ischio-rectal fossa and retained for three days; highest temperature 101°, which was not as high as it sometimes had been before the operation; primary union, except at a very small point at the anterior portion of the wound.

Final result: He had very good control over the contents of the rectum except when the bowels were loose, which did not occur often. He gained in weight and his general health was excellent, so that he attended to an active business, but suffered from repeated attacks of tic douloureux. I saw him occasionally for two or three years.

January 25, 1895. I have just learned that he died a few days ago of acute diarrhea under the care of a homeopathic physician. There was no return of the disease so far as I could learn, although there was only lacking a month of four years since the operation.

CASE XII.—*Amputation of two and a half inches of the rectum and anus by the perineal route. Recovery.*

B. R., aged forty-three, entered the Jefferson Hospital March 2, 1891. Family history good. For fourteen months he had had severe pain in defecation. Operation March 5, 1891, two and a half inches of the rectum were amputated, including the anus. The peritoneum was not opened. The end of the bowel was sutured to the perineum. Healing by first intention. A recent letter has been returned with information that he is probably dead.

CASE XIII.—*Amputation of five inches of the rectum by the perineal route without prior colostomy. Peritoneal cavity not opened. Artificial sphincter by Gersuny's method followed by infection. Recovery.*

Mr. R., aged thirty-three, Philadelphia, Pa., was admitted to the Jefferson Hospital May 22, 1894. Family history good. Ten years previously he had malaria and dysentery, and three years later gonorrhea. Four years previous to admission he received a bad bruise in the region of the anus by sitting down upon the knob of a faucet. A year prior to this accident he noticed that his stools were gradually becoming smaller in diameter, and once in a while he noticed clots of dark blood and mucus, all of which were attributed to hemorrhoids. The pain in defecation gradually increased. Within the last year the fecal masses had been reduced to the size of a lead pencil, and he had had alternate constipation and diarrhea. On examination I found a well nourished and apparently healthy man, with a fair appetite, suffering no pain excepting on defecation. By rectal touch an evidently malignant growth was felt, beginning just within the anus and at a point two and a half inches above the anus; the stricture was so tight as not to be permeable by the finger. Urine negative. For a week he was in bed, during which time the bowels were carefully evacuated and his diet regulated.

Operation May 24, 1894. An elliptical incision was made around the anus, extending posteriorly to the tip of the coccyx. The rectum was then separated partly by scissors and partly by blunt dissection until healthy tissue was reached. The dissection was very difficult on account of the adhesions, but was facilitated by splitting the rectum and carrying the left forefinger up into the gut. It was not necessary to remove the coccyx. In the anterior part of the wound were dis-

closed the bulb of the corpus spongiosum, all of the prostate gland, and a considerable portion of the bladder. Although five inches of the rectum were resected the peritoneal cavity was not opened. The stump was twisted 180 degrees and fastened to the skin by very close stitches. In front of the rectum and behind it gauze packing was inserted. The calibre of the rectum itself was also packed with a considerable pledget of iodoform gauze to prevent the escape of fecal matter and infection. The stitches gave way and infection of the wound took place. The temperature, which up to that time had been about 100°, on the twelfth day rose to 102.4°, but fell to the normal in two days. He was discharged from the hospital on July 3, the entire wound being healed excepting a small sinus in front of the anus.

March 1, 1897. Two years and ten months have now elapsed since the operation, and he writes me that there is no evidence of any recurrence, that he has "fair control over his movements and always has warning at time of stool, of which he has about two or three a day." There is no protrusion of the bowel and only a trifling mucous discharge. His general health is excellent.

CASE XIV.—*Cancer of anus and rectum. Removal of V-shaped portion of bowel, including the sphincter, by the perineal route. Recovery.*

Joseph N., aged twenty-nine, was admitted to the Jefferson Hospital March 10, 1896. His family history is good. Two years prior to admission he had a fistula *in ano*, which was operated on, but left an ulcer which never healed. On examination I found a very marked indurated chronic ulcer of the rectum just within and partly involving the sphincter in the median line posteriorly.

Operation March 11, 1896. I removed a V-shaped portion of the anus and rectum, the apex of the V being an inch and three-quarters from the anal margin. The portion of the sphincter excised was nearly an inch. The mucous membrane was stitched together, special care being taken to see that the ends of the sphincter muscle also were well approximated. Before the operation a tampon of iodoform gauze was pushed up into the rectum to keep the wound clean, and was left there for three days after the operation. A small amount of opium was given daily to constipate. March 30, 1896, he was discharged almost well. The sutures had cut out to a small extent and produced a little local raw surface. He is still living.

Dr. D. Braden Kyle examined the specimen and pronounced it a squamous-celled epithelioma.

*CASE XV.—Resection of four inches of the rectum and sigmoid flexure by abdominal section. Approximation by Murphy's button only partially practicable by reason of the silk thread catching in the thread of the screw. Appendix also removed. Sloughing of the bowel. Death on the third day.*

Mrs. W., aged thirty-three, was kindly sent to the Jefferson Hospital by Dr. Vaughan, of Middletown, Del., November 19, 1894. Her maternal grandfather died of cancer of the stomach; otherwise her family history was good. She had not lost weight. She always enjoyed good health till September 1, 1894, when she had an attack of cholera morbus. This was followed by what was thought to be an appendical abscess, as she passed considerable pus by the rectum. She had been very much constipated ever since, and for two weeks had no movement of the bowels. There had been considerable nausea and vomiting, not fecal in character. She suffered from much flatulence and tenderness, especially in the right iliac fossa. Her temperature had been normal or even subnormal constantly, excepting for two days, when it rose to 100.6°.

A careful examination of the rectum gave no information. The abdominal wall was so thin that the coils of intestine and their active peristalsis were easily seen. No tumor could be discovered anywhere. Various purgatives and enemata were tried for ten days in order to unload the bowels; high enemata were then used by Hegar's method. The largest amount which could be injected was a quart; more than this caused considerable pain. This however at last enabled me to discover the source of the trouble. The enema by this method with the pelvis raised forced from the pelvis into the abdomen a lump about two inches in diameter. The tumor was movable; it was just above and to the left of the pubes. By various means the bowels were gradually unloaded, but the tumor still remained.

Operation December 7, 1894. In view of my ability to displace the tumor from the pelvis into the abdomen, I determined to operate by way of the abdomen. This was opened in the middle line and the appendix first explored. This was found to be nearly five inches long, very much twisted, and completely filled from one end to the other with a row of oval fecal concretions. Deeming this

a very probable future danger the appendix was removed. The sigmoid flexure was very long, the loop reaching over to the right iliac fossa; its walls seemed to be markedly thickened. Passing the hand into the pelvic cavity I was able to draw out the tumor already alluded to. This was a puckered mass on the anterior side of the colon and was so low down that it was with great difficulty that it could be drawn out of the pelvis sufficiently for operation. Below the tumor, the sigmoid and rectum were narrowed, but from the tumor upward for about fifteen inches the whole of the descending colon and the sigmoid flexure were thickened, especially at the longitudinal bands. I was quite uncertain whether the whole mass was cancerous or whether the thickening might not result from the former inflammatory attack, but as I found the mesenteric glands enlarged I thought it wise to excise the tumor and the adjacent most markedly diseased colon. Four inches of the bowel therefore, including the nodular mass, were resected, a small V-shaped portion of the mesentery being taken out, the apex of which was only about an inch from the colon, and an end-to-end anastomosis was then effected by a Murphy button. The lower half of this fitted into the calibre of the bowel rather snugly, but the upper end of the bowel was so dilated and thickened that there was great difficulty in inverting the end satisfactorily. Moreover, when I attempted to approximate the two halves of the button, after they had approached each other about half the proper distance, I found that I could not approximate them any further. Accordingly, I surrounded the button with two rows of Cushing's right-angled sutures. Dr. D. Braden Kyle, to whom the specimen was given for examination, reported that it was a tubular epithelioma.

Immediately after the operation fecal movements began. In the first twenty-four hours she had nine, not diarrheal, but of soft feces, and in the next twenty-four hours there were seven movements, and a few more afterwards. On the evening of the second day when I saw her she was bright and cheerful, her temperature was normal, her stomach had quieted entirely, and there was no pain. At 10 P.M. she was suddenly seized with violent abdominal pain, passed into collapse, and died at 10 A.M. on the third day.

The autopsy showed that the stitches had held, but that an inch and a half of the upper dilated end of the bowel had sloughed

and caused perforation. On removing the button I found the obstacle to complete approximation of the two halves lay in the fact that one end of the silk ligature around the collar of the button had been caught between the two tubes as one was thrust into the other, and when it was drawn taut no further approximation of the halves could be made.

Abbe (*Annals of Surgery*, January, 1895, p. 71) has reported a similar case. The unexpected difficulty that I had points to the fact that we ought to see that the two ends of the silk are cut short enough not to catch in the thread of the screw.

CASE XVI.—*Inoperable carcinoma of rectum. Lumbar colostomy. Death in about two years.*

John W. F., of Washington, D. C., was first seen at the request of Dr. S. Weir Mitchell June 8, 1885. Six weeks before he thought he had piles, as a small amount of blood was seen in his movements. The fecal masses were of good size. He had bearing down pains, especially marked in the sacral region, with a sense of fulness in the rectum, though there was little or no pain. Four inches above the anus posteriorly a tumor was felt. It stretched two-thirds around the rectum and was firmly attached to the sacrum; was hard, irregular, and nodulated. I regarded the case then as inoperable. In about five months the cancerous circle was completed. A year later a lumbar colostomy was done by another surgeon. This relieved him greatly. He died about two years later.

CASE XVII.—*Inoperable cancer of the sigmoid and rectum. Right lumbar colostomy. Peritoneum opened; great difficulty in deciding upon which was the colon and which the small intestine. Operative recovery; death about a year later.*

Mrs. W., aged sixty, wife of a physician living in Minnesota, consulted me in the winter of 1887. She had suffered for nearly a year with constipation and diarrhea, with diminished fecal masses and a great deal of pain in the left inguinal and sacral regions. She had lost considerably in weight. The instant that the fingers were placed upon the left lower abdomen, just at the upper border of the pelvis, a long sausage-shaped tumor was found, the lower end of which was lost in the pelvis, the upper end reaching a little above the anterior superior spine. By the rectum the finger could just touch the lower border of the growth. The diagnosis was evident and no radical operation possible. Accordingly, I did upon her a lumbar colostomy, in the right lumbar region. I was unable to find the colon

without opening the peritoneum. When I opened it two coils of intestine presented themselves. I was utterly unable to distinguish at first which was the colon and which the small intestine. I was unable to recognize any longitudinal bands in the colon *in situ*, and the colon could not be drawn out sufficiently to enable me to see them. Finally, as the result proved, I decided on the right one, more I am bound to say by good luck than by good judgment. She died about a year later. The difficulty which I had in this case decided me positively, therefore, to abandon lumbar for inguinal colostomy. In addition to this the advantages of inguinal colostomy, which I think are very many, almost decided me independent of the difficulties experienced in this case.

CASE XVIII.—*Inoperable cancer of the rectum. Lumbar colostomy. Recovery. Death twenty-four days after operation from acute entero-colitis.*

George C., aged forty, Beverly, N. J., was kindly referred to me at the Jefferson Hospital by Dr. J. B. Walker, of Philadelphia, on May 11, 1891. Best weight 169 pounds, in August, 1890; present weight 137 pounds. His history showed chronic constipation. In August, 1890, he consulted a physician, who said that he had trouble in the sigmoid flexure. When Dr. Walker first saw him just prior to his admission to the hospital he discovered a lump at that point. The tumor was the seat of a dull ache, with shooting pains down the left leg.

On examination a tumor was felt in the left iliac fossa, and when the finger was passed into the rectum the tumor was felt about two and a half inches above the anus; reciprocal pressure could be felt both above and below. The disease being so very extensive I deemed it inoperable and advised a left lumbar colostomy. This was done on May 26. The bowel was not opened for three days, as there was nothing urgent about the case. He left the hospital June 5 entirely recovered. A very sudden change of the weather took place the day he left the hospital, and he apparently took cold, fell severely ill of an entero-colitis, and died two weeks later.

CASE XIX.—*Inoperable cancer of the rectum. Inguinal colostomy by Maydl's method. Bowel opened in six hours; great relief. Death from exhaustion thirty-one days after the operation.*

Miss C. B. was seen in consultation with Dr. G. R. Morehouse February 17, 1893. There had been absolute obstruction for

eleven days, excepting that the enemata used had brought away small masses of fecal matter. The abdomen was so much distended as to interfere with respiration, and there was every evidence of impending speedy dissolution. A small bed-sore existed over the sacrum, and the patient was emaciated to the last degree. Rectal touch showed that the rectum was full of solid feces, and the tip of the finger discovered a cancerous mass. As she had no power to expel the contents of the rectum they were removed piecemeal by the finger and a spoon-handle. This being done, the hard mass was felt as a nodular growth, the mouth of which was so softened that the disease could be broken down by the finger-nail. Evidently radical treatment by excision could not be entertained for a moment; a palliative operation would be all that could be done. Accordingly, the same day a Maydl operation in the left iliac fossa was done in a very few minutes. Six hours after the operation the bowel was opened with the Paquelin cautery without hemorrhage. The adhesions were perfect. Small quantities of gas and feces were passed in the next twenty-four hours, with great relief. The subsequent comfort that she had entirely warranted the operation. Two weeks after the operation I removed the glass bar and tied the mesenteric portion of the bowel by a rubber band. Forty-eight hours later I completed the division by the scissors. The feces between the artificial anus and the rectal tumor were partly voided through the artificial anus, but most of them mechanically by the finger. Her strength failed gradually, and she died from exhaustion March 20, thirty-one days after the operation.

*CASE XX.—Extensive carcinoma of rectum and colon. Palliative right inguinal colostomy (Maydl's method). Recovery from operation. Death from exhaustion fifteen days later.*

Mrs. D., aged forty-four, was sent to the Jefferson Hospital January 15, 1895, by Dr. R. Wallace of East Bray, Clarion Co., Pa. She ceased menstruating one year prior to this date; was always in good health until two years before, when she had what was thought to be a fissure of the anus. On dilating this, a stricture of the rectum was found. Her health had gradually failed, and in the last two months she lost eight to nine pounds; color sallow; appetite poor; pain on defecation intense and continuous. The pain extended over the entire sacral region. On examination I found that as far as the finger could reach there was an extensive carcinoma

of the entire bowel, involving the whole of the recto-vaginal septum, but not the vagina itself. Abdominal palpation revealed no tumor. Her general health was so poor and the disease so extensive that I very quickly made up my mind that nothing could be done excepting in the way of palliation. Accordingly, on January 23, 1895, I opened the abdomen in the left region to determine whether the colon was healthy, and if so to make an artificial anus by Maydl's method. As soon as the cavity was opened I found that the descending colon was studded with growths of a size somewhat smaller and larger than a pea. The wound was immediately closed and the abdomen opened on the right side, where the Maydl operation was done. Three days later the bowel was opened transversely to one-third of its circumference by scissors, and some vessels tied. A week later the glass bar was released by cutting through the remaining portion of the bowel. My object in waiting a week was to allow of such firm adhesions that there would be no danger of the bowel falling back into the abdomen. The operation gave her great relief, but her strength failed very rapidly, and she died on February 7, 1895, fifteen days after the operation. Before the operation her temperature had risen to 103.2°, but immediately afterward fell to 100° and below. I made some cultures from the abdominal cavity, and these Dr. Kyle reported showed both staphylococcus and the bacillus coli communis, though there was no suppuration either before or after the operation. The infection may have been an accidental one at the time of operation, but every possible means were taken to prevent it.

*CASE XXI.—Inoperable carcinoma involving the caput coli, ileum, sigmoid flexure, and rectum. Celiotomy. Artificial anus made in the ileum by Maydl's method gave relief and lowered the fever. Death on fifth day.*

Mrs. G. B. R. was first seen in consultation with Dr. Eleanor C. Jones March 20, 1896. Aged thirty-seven; present weight 95 pounds; best weight 110 pounds two years ago. Her family history was excellent. On September 1, 1895, she first observed distinct pain in the rectum. In the course of a couple of months she observed that the feces were streaked with blood. No diminution in the size of the fecal masses had been observed. On October 30, 1895, she was examined by Dr. Broomall and Dr. Jones together, and they observed nothing abnormal in the rectum. On March 9, 1896, she had been etherized by Dr. Jones and a small tumor found on the an-

terior wall of the rectum just within reach of the finger. Scrapings from this were taken, and Dr. Robert Formad reported them to be carcinomatous, which report was confirmed by Dr. Kyle. Dr. Jones had examined her blood and found the hemoglobin to be sixty per cent., and that no plasmodium existed. The urine was negative, and both urine and stools were free from tubercle, as also were her lungs.

Examination March 20, 1896. I found a rather slender and feeble looking, though sprightly, woman. The rectal tumor alluded to was readily found on the anterior wall of the rectum just above the upper end of the vagina. It was quite tender to the touch, and no satisfactory examination could be made as to its size or its relation to the uterus or the ovaries. On examining the abdomen another small lump as large as a large cherry was felt just below the right border of the ribs in the nipple line. Pressure by the finger appeared to locate it in the abdominal wall, though it might have been more deeply situated. She was then etherized. The rectal tumor extended into the pelvis and was evidently a carcinoma; I could just reach it with my finger on deeply depressing the perineum. By bimanual examination it seemed to be continuous with the uterus, and I judged that the two were adherent. She absolutely demanded an operation, preferring to take the chances of dying to living the wretched life that she had before her. I decided therefore to operate after building her up as much as possible.

Operation April 10, 1896. The last mandate that she gave me as I left her room before the etherization was: "Mind that you take it all out." A celiotomy was done in the median line below the umbilicus. I found a mass two-thirds the size of a fist uniting the caput coli, the lower part of the ileum, a coil of the sigmoid flexure of the colon, and still lower down the rectum. On its surface ran the appendix four inches long, but about twice the normal diameter. The tumor did not encroach seriously on the calibre of the bowel. It lay immediately behind the uterus, but was not adherent to it. Both ovaries were markedly sclerotic and cystic. Removal of the mass was utterly out of the question. Accordingly I made an artificial anus in the lower ileum about twelve inches from the caput coli by Maydl's method. Before doing this, however, I examined the tumor felt at the border of the ribs and discovered that it was a distended gall-bladder,

and that there was a stone as large as the last joint of the thumb in the cystic duct. As it gave her no trouble and her life would evidently be short I did nothing with it. A coil of the ileum was now drawn out and the skin stitched together through a hole in the mesentery after the recommendation of Bidwell (*Lancet*, 1895, ii, 753). On the third day after the operation the intestine was opened, and this gave her great relief. Her strength however failed, and she died five days after the operation. Prior to the operation her temperature had risen as high as 102.4°, but after it and until just before her death it never rose above 100°.

CASE XXII.—*Cancer of rectum. Palliative colostomy only, on account of cardiac and costal complications. Schleich's fluid used instead of ether. Recovery.*

Hiram F., aged sixty-five, was kindly referred to the Jefferson Hospital by Dr. C. H. Shivers, of Haddonfield, N. J., March 1, 1896. Family and personal history excellent, except that when in the army in 1861 he had some vague heart trouble and had never been able to do any heavy work since, nor for the last fifteen years had he done any work. A year before he noticed a burning sensation about the rectum, which gave him great pain after defecation. He had lost about twenty pounds in weight in two years. Two and a half inches above the sphincter an indurated cancerous mass was found entirely surrounding the rectum. The case was one eminently fitted for extirpation, probably without any resection of the bones except possibly of the coccyx; but I decided on a colostomy by Maydl's method, for the following reasons: first, his heart was almost certainly fatty, as was determined by Dr. J. C. Wilson, who kindly saw him with me; second, his pulse was very weak and intermittent; third, the cartilages of the ribs were entirely ossified and the lower ribs united to each other, so that the chest-wall moved very imperfectly, and only as a whole up and down and to a slight extent. This greatly interfered with his respiration.

Operation March 4, 1896. For the reasons given above I also disliked to use ether or chloroform, and accordingly used Schleich's fluid, which only answered moderately well, dulling the pain but not annulling it. He felt pain not only during the incision of the abdominal wall, but also when the colon was handled. Instead of a glass bar I sewed the skin together by two stitches as suggested by Bidwell (*vide supra*). On the second day after

the operation the bowel was opened through half its circumference, and on the ninth day was completely divided. He had no rise of temperature after the operation. I have not heard from him since.

CASE XXIII.—*Cancer of rectum. Palliative colostomy by Maydl's method only, on account of the condition of the blood. Schleich's fluid used instead of ether. Relief; recovery from operation. Death thirty-seven days later from gangrene of foot from femoral venous thrombosis.*

Mrs. C. E., Stroudsburg, Pa., aged forty-three, was kindly brought to me by Dr. B. F. Keller of Pottstown, Pa., and Dr. C. M. Brownell of Stroudsburg, October 14, 1895. Her mother died of cancer and her grandmother of a tumor presumably malignant. In the middle of July, 1895, she noticed a sore feeling low down in the back, and that it hurt her to sit down. Her passages lessened in amount, but increased in frequency to two or three times a day. The size of the fecal masses also, was diminished. There was a slight mucous discharge from the anus. Rectal touch showed the rectum to be entirely surrounded by an extensive cancerous mass at two and a half to three inches above the anus. The finger could be engaged within the mass, but I was uncertain whether it reached its upper edge. No adhesions seemed to exist either to the uterus, vagina, or sacrum. Her general health seemed quite good, and I recommended extirpation. On November 7, 1895, she came down to my hospital, but with a marked change in her condition. Her lips and fingers were blue and livid, though there was no cardiac disease. Both legs were much swollen, and on examination I found a large thrombus in the right femoral vein and a moderate one in the left. In view, therefore, of the state of her blood, which became thrombosed with such ease, I instantly decided against any radical operation, and recommended a Maydl operation by a local anesthetic with Schleich's fluid.

Operation November 9, 1895. Two ounces of the medium solution of Schleich were injected under the skin and then into the muscular tissues of the abdominal wall. The operation was attended by no pain excepting at the upper end of the incision for perhaps a quarter of an inch, where I got beyond the area of the anesthesia. No pain was manifested on manipulating the colon (none of the fluid had reached the abdominal cavity or contents), and the operation was completed without difficulty, the bowel being stitched to the abdominal wall at the upper

and lower margins by one suture. Two days afterward the bowel was opened with the scissors without pain or bleeding. On the fifth day the protruding part of the colon was cut away, so that the end projected only half an inch above the level of the skin. On the evening of that day she was suddenly seized with great pain in the right leg, which became pale and cold, evidently from a marked extension of the thrombus. The temperature rose to 102°. The leg was elevated, wrapped in flannel and cotton, and surrounded with hot fomentations and hot-water bags. Internally hot stimulants and tonics were administered. In four days the temperature had fallen to the normal, and she went home ten days after the operation. Shortly after leaving the hospital gangrene of the left foot set in, and she died December 16, 1895, thirty-seven days after the Maydl operation.

Through the courtesy of Dr. Wm. J. Taylor I append two other cases in which the palliative Maydl operation gave great relief: the one for a short time before death; in the other the patient's life was prolonged for three years.

CASE XXIV.—*Inoperable carcinoma of the bowel. Inguinal colostomy (Maydl's operation); great relief. Death two months later.*

Mr. P., Philadelphia, was first seen by me in consultation with Dr. Willard on May 21, 1895. For a long time he had been suffering with, as he supposed, hemorrhoids, but which proved eventually to be carcinoma of the rectum. When Dr. Willard first saw him it had gone beyond the point of successful operation, and accordingly, on May 22d, he curetted the growth in the rectum in order to overcome the obstruction, which was pronounced and painful. Following this, on several occasions I learned that curetting was done, each time with relief, the degree of which gradually lessened with the progress of the disease. In the summer of 1896, while at the seashore he came under the professional care of Dr. Wm. J. Taylor, who on September 1 did a Maydl operation in the left inguinal region, after which he made a very speedy and satisfactory operative recovery. The bowel was opened after fourteen hours. After he returned to the city I saw him on several occasions. The relief from the operation was very great. His strength gradually failed, and he died on November 6, 1896.

CASE XXV.—*Inoperable cancer of rectum. Inguinal colostomy (Maydl's method); great relief for three years till he died.*

Rev. Mr. D., aged sixty-six, had been treated for hemorrhoids for several years. For fifteen months past the stools had been streaked with blood. A very extensive cancerous growth in the rectum was discovered by touch on his first visit, October 15, 1892.

Operation October 19, 1892, by Dr. Wm. J. Taylor. He took ether with very great difficulty and required artificial respiration during the operation, which was rapidly performed. Several hard cancerous nodules were found in the descending colon. The bowel was opened on the seventh day by the cautery. He made a prompt and satisfactory recovery. No radical operation, of course, was attempted. Two years after the colostomy his general health was good, and he reported "not much trouble from the wounds." He died September 29, 1895, almost three years after the operation. Some time before his death the cancer, which had extended to the bladder, resulted in a recto-vesical fistula.

#### • ETHER AND CHLOROFORM.

In a letter to the editor of the *Journal of the American Medical Association* of January 16, 1897, Dr. CHENERY of Boston says that a few weeks ago he saw an article stating that a number of deaths by chloroform had occurred in women in confinement. Not long before he saw it stated that no such case is on record. Now, which of these writers is correct? Has chloroform killed any woman under such circumstances? Chenery has no remembrance of seeing such an instance reported. If both ether and chloroform cause death in such cases we must select accordingly.

There are several points, however, we may properly consider as between the two:

1. An etherized patient, unless thoroughly under its influence, must be regarded as drunk or crazy, requiring considerable assistance to control and take care of her. It is not so with chloroform; the patient rather likes it and will call for it when not given to full anesthesia, and is able to think and talk and help the physician. The assistance of the nurse and one other woman is all the help required. He puts the chloroform on the handkerchief and keeps watch of the patient. The whole apparatus required is a lady's pocket-handkerchief, folded as it comes to hand, and a small phial, having a small neck, for the chloroform. Then placing the kerchief firmly over the mouth of the phial, the bottle is inverted so that only a few drops escape on to the kerchief. This bottle he keeps within reach and handles

himself, using his left hand and removing and inserting the cork with his teeth. Thus any woman can hold the chloroform to the patient, returning the kerchief to him for renewal of the chloroform just preceding the next pain, and keeping the kerchief to the nose in the intervals of the pains. Thus more or less of the anesthetic can be used as the exigency requires to keep the pains bearable. If more chloroform has to be given during the last few pains that does not seriously affect the child. And even in instrumental cases it is rare to need any extra skilled help, for by the time this is reached the woman giving the chloroform has become quite competent to give the anesthetic herself.

2. In heart cases chloroform has the advantage over ether.

3. Chloroform is not so dangerous to the child, since the mother takes less of it to make her confinement comfortable, and the child is rarely but slightly anesthetized as compared with ether, and speedily, in most cases, responds to changed circumstances and begins to breathe. Even in the heavier anesthesia of instrumental cases, the time being short, there is usually little difficulty in bringing about respiration in the child, if the chloroform is laid aside and the cord is not cut. Chenery remembers but one child over which he worked many minutes before respiration was established. This mother was a particularly nervous woman and required considerable anesthesia, and it was continued a much longer time than usual. When Chenery hears of a stillbirth, the child being alive before, he always inquires if the mother did not take ether at the confinement, and this is generally answered in the affirmative.

4. Ether, by its greater stimulation of the circulation, he believes is much more liable than chloroform to be followed by hemorrhage.

Chenery thinks these four points are greatly on the side of chloroform. If it is safer for the mother it becomes almost imperative that the accoucheur should give it instead of ether in confinement cases; for if judiciously administered it is a most glorious blessing to suffering humanity. Etherization is a home invention, and the writer entered Harvard only a few years after its first application, and has witnessed the continuous prejudice in its favor ever since. Yet from his own judgment and experience he is strongly in favor of chloroform in confinement cases, and from its easy application he believes we ought not to hesitate to use it when we should be slow to begin with ether.

### THE VALUE AND DANGER OF CANTHARIDES.

It has been our custom from time to time to point out in the editorial and progress columns of the THERAPEUTIC GAZETTE certain of the untoward effects, produced by drugs which are commonly employed. Thus our readers will remember that in one editorial we called attention to some of the peculiar and disagreeable influences exercised in susceptible persons by quinine, and in another editorial those caused by iodide of potassium.

In the case of cantharides, a drug which is employed so frequently, it is of importance to recognize the fact that it not only possesses much power for good but also, in persons with easily irritated kidneys, the possibilities of producing deleterious effects not only when it is administered internally by a dermatologist for certain skin lesions and by the ordinary clinician for certain low grade inflammatory processes in the kidney, but also when it is applied externally for the purpose of producing counter-irritation and vesication. Whatever may be the opinion of the

best therapists as to the value of cantharides in minute doses for controlling or overcoming albuminuria due to subacute or chronic parenchymatous nephritis, there can be no doubt in the minds of the majority of physicians that the external use of this drug over the renal region in cases of congestion of the kidneys is often followed by the most beneficial results. Personally the writer of this editorial is convinced that the internal use of cantharides for the relief of albuminuria is resorted to too infrequently, since in quite a large number of cases he has seen beneficial results follow its employment; nor is he alone in this conclusion, for some of the English therapists have gone so far as to recommend minute doses of the tincture of cantharides for hematuria depending upon acute inflammation of the kidney after the first blush of its severity has passed by. Quite recently Du Cazal in one of the French journals has strongly supported this use of cantharides, having followed the recommendation made by Lancereaux in employing this method. Out of five cases, all of which followed attacks of infectious diseases, such as pneumonia and scarlet fever, four entirely recovered from the albuminuria. As pointed out, however, by Saundby in the *Birmingham Medical Review*, the results of Du Cazal are by no means as positively favorable as they would appear at first glance, for in many instances persons suffering from the albuminuria due to the infectious diseases recover without treatment, provided ordinary care is taken as to hygienic living, diet, and protection from cold. Saundby, on the other hand, states that he tried cantharides systematically in cases of nephritis some years ago, and came to the conclusion that it exercised no specific effect in controlling the excretion of albumen.

In regard to the possibility of deleterious influences following the employment of cantharides externally, a case which has recently been reported by Huchard is of considerable interest. It was that of a girl of eighteen to whose epigastrium was applied a small blister six square centimeters in size. As a result of this she developed an acute nephritis, with anasarca, intense dyspnea, convulsions, and almost complete uremic amaurosis, and associated with these symptoms she also had almost complete suppression of urine. He also mentioned two fatal cases caused by the application of cantharidal blisters, and what he said in denunciation of this form of counter-irritation was supported by two other

practitioners who were attending the meeting at which Huchard made his report.

On the other hand Dr. Ferrand, a practitioner who also joined in the debate, pointed out what Saundby and others know full well, namely, that blisters were useful and not dangerous, *unless they were left on too long*. It seems to us that the physician who desires to employ a cantharidal blister should remember two facts, namely, that blisters of large size are contraindicated in the presence of renal irritation or inflammation, and that in any event they should not be allowed to remain in contact with the skin longer than is necessary to produce the vesication. If these facts are borne in mind the evil effects which are feared by Huchard will not be met with, and patients will not be deprived of a useful though painful therapeutic measure owing to the fear of the physician that an accident may occur.

Convinced though we are that vesication is of value in the condition which we have named, we do not believe that it is to be employed recklessly or when milder counter-irritants such as the ordinary rubefacients would do as well. In Huchard's case the cantharides were applied to relieve gastralgia. Again, we think that the profession is gradually coming to the view that the application of cantharidal blisters to the walls of the thorax in the treatment of pneumonia and pleurisy, except in the very earliest stages, are of little real therapeutic value and frequently cause the patient a great amount of pain and annoyance. In children who are suffering from thoracic inflammations blisters certainly ought not to be employed, first, because of the pain; second, because of the nervous irritation which they produce; third, because if the child is ill for a considerable period of time difficulty may be met with in healing of the sore; and lastly, because renal irritation and irritative fever are apt to be caused by the external use of this drug in this class of patients.

#### *CARBOLIC ACID AS A DISINFECTANT.*

---

Nearly twelve years ago the Committee on Disinfectants of the American Public Health Association, composed of eminent bacteriologists and those interested in public health, made a report which while it received widespread notice did not receive the attention that its importance demanded. In this Report they included the results of a long and

careful series of experiments designed to determine the disinfectant or germicidal value of nearly all of the substances which are commonly used for the purpose of destroying germs, and it will be remembered that as a result of their labors we were confirmed in our earlier belief that bichloride of mercury, in proper solution and in proper surroundings, formed at once the most useful and powerful of all disinfectants. Also that for the disinfection of large masses of material and for cheapness and efficiency chlorinated lime when freshly prepared and containing due proportions of chlorine formed the next best disinfectant, and in many respects was superior to corrosive sublimate itself.

These same studies, moreover, proved beyond doubt, as have many subsequent ones made in other countries, that carbolic acid has a reputation as a germicide far above that which it deserves; that the ordinary solutions of carbolic acid are almost useless as germicides, though they were active as antiseptics; and that it requires very many hours exposure to very strong solutions of carbolic acid to kill pathogenic germs. Notwithstanding these studies, however, and notwithstanding the fact that surgeons have for a number of years ceased to employ carbolic acid for surgical purposes, to the extent that they did previously, the laity and some members of the profession seem to regard carbolic acid as the ideal disinfectant and scatter it about premises and rooms in a manner which, while it assails the nostrils of the individual, does little towards protecting him from infection. Further than this, carbolic acid can be obtained at any drug store in any quantity upon the request even of a child, and is generally sold without a question being asked as to the purpose for which it is intended. In other words, the laws regarding the sale of poisons do not include carbolic acid in the list of those which shall not be sold without a physician's order. Further, very few of the laity, and some of the profession, seem to be ignorant of the fact that carbolic acid while it is a poor disinfectant is on the other hand one of the most rapidly acting and lethal poisons known, capable of destroying life within a very few minutes after its ingestion, or of causing death later on by reason of the primary and secondary changes which it produces in the body. In 1892 we called attention to this fact in a leading article in the *THERAPEUTIC GAZETTE*, our attention being once more called to the matter at that time by the report of four cases of carbolic

acid poisoning in *The Chemist and Druggist* for that year.

Our attention has again been called to this matter by an interesting paper by Dr. J. Dixon Mann, Professor of Forensic Medicine in Owens College, Manchester, upon "Some Statistics of Carbolic Acid Poisoning," which is published in *The Medical Chronicle* for December, 1896. After mentioning a number of facts which we have already spoken of and pointing out how frequently carbolic acid is handled carelessly and placed in the way of children and ignorant members of the laity, Dr. Mann publishes a table in which he shows that from 1885 to 1895 the total number of deaths from this poison in Great Britain amongst males was 176 and amongst females 109; 52 of the males were in children under five years of age, and 26 of the females were under five years of age. He then goes on to point out that carbolic acid stands fourth among the poisons by which death was accidentally or negligently caused during the ten years ending 1894, and if chloroform and lead, the first of which has produced accidental death in a large number of cases and the second of which produces poisoning in the arts, are excluded carbolic acid takes the second place among the poisons which have caused accidental death from personal carelessness or ignorance.

Again, Dr. Mann points out that in the ten years which we have mentioned one-fourth of the women who committed suicide by poison did so with carbolic acid, and it ranks second as a suicidal poison for males; while if the two sexes are taken together carbolic acid stands first of all poisons used for the purpose of committing suicide. It is also interesting to note that the number of people who commit suicide by means of carbolic acid has rapidly progressed each year: thus in 1891 there were 63; in 1892, 73; in 1893, 117; and in 1894, 167. He also mentions two cases in which carbolic acid was used for the purpose of committing murder, the victims being children; and two cases of manslaughter also occurred.

Finally, he sums up the facts that during the ten years we have named 917 deaths were due to carbolic acid, an average of nearly 100 deaths; and that in 1894 the number of deaths from this cause reached the appalling total of 202.

Dr. Mann urges, therefore, what we have previously urged, that a restriction should be put upon the sale of this violent poison; and we doubt not that an examination of statis-

tics in this country would give conclusions nearly identical with those obtained by Dr. Mann from a study of the statistics in the United Kingdom of Great Britain.

#### THE USE OF THYROID EXTRACT AND ITS SUBSTITUTES.

---

The thyroid gland having become a recognized and valuable therapeutic agent in the treatment of several grave, although comparatively rare, affections, there have naturally been many studies made with the object of decreasing the bulk of the ordinary dose and of preparing the gland or its extract so that its administration would be as unobjectionable as possible. With this in view there have been prepared capsules containing concentrated extract of thyroid and tablets containing desiccated thyroid gland of such small bulk that one tablet containing two grains is equivalent to five grains of the fresh gland; and these tablets and capsules, or the desiccated gland itself, have been used for many months with the greatest possible satisfaction in the treatment of myxedema, cretinism, and obesity of certain types.

Not satisfied, however, with the use of the gland in this form certain German investigators have endeavored to isolate from it its so-called active principles and to market these derivative substances in small bulk, accompanied by the statement that they in every way represent the activity of the gland itself.

Clinical results, however, do not indicate that their theoretical views concerning the activity of these derivatives are correct, and not only is this true, but careful physiological study indicates positively that their influence upon general bodily metabolism is quite different from that exercised by the complete gland. It seems evident, therefore, that the entirely unobjectionable whole gland prepared in desiccated powder or capsule or in compressed tablet is the only means by which we ought to attempt to treat myxedema and similar conditions in which this animal substance has been found useful.

---

#### THE SURGICAL TREATMENT OF PERFORATING TYPHOID ULCER.

---

Two noteworthy contributions have appeared upon this topic, one—the most important and thorough—by Finney of Baltimore (*Annals of Surgery*, March, 1897), the other by Monod and Van Verts (*Revue de*

*Chirurgie*, March 10, 1897). Finney states that Richter in 1762 first suggested the advisability of opening and draining the peritoneal cavity in cases of general suppurative peritonitis. The first operation undertaken in a known case of typhoid fever was performed, he states, by Leticke of Strasburg. A wedge-shaped piece of the intestine was excised and the bowel sutured. The patient survived but a few hours. Finney has since collected forty-six cases reported in the literature upon this subject, and adds to this number six hitherto unpublished cases, including three of his own—in all fifty-two cases. From a study of statistics he finds that perforation of the intestine occurs in from one to two per cent. of all typhoid-fever cases, and as a cause of death in fatal cases it is found in between six and seven per cent. It occurs in the ileum, usually in the last two feet, in over eighty per cent. of all cases; in the large intestine in more than twelve per cent.; in the vermiform appendix in about five per cent. of all cases. It is usually single, but may be multiple. There seems to be no definite relation between perforation and the severity of the attack. It takes place in the mild as well as in the severe cases; the symptoms marking its onset may be sudden and severe or very mild, and are at times even wanting. It is more frequent in men than in women in about the ratio of three to one, and is rare in children. It commonly occurs between the ages of twenty and thirty and in the third week of the disease. The duration of life following this accident is short. Over eighty-three per cent. of all cases die during the first week.

Peritonitis resulting from perforation, if local, may result in spontaneous cure. It is possible for peritonitis to develop from causes other than perforation. Thus it may be due to ruptured mesenteric glands, abscess of the liver, perforating ulcers of the gall-bladder, softened infarcts of the spleen, etc. It is therefore evident that an estimation of the percentage of recovery is impossible.

Including all the cases that have been reported as operations for perforating typhoid ulcer, together with the six cases which he has collected himself, Finney states that the percentage of recovery is 32.68; [excluding however all doubtful cases 45 are left, of which 11 recovered, a percentage of 26.22.

Finney believes that his investigation does not throw much light upon the still mooted question of the respective merits of irrigating or wiping the peritoneal cavity. He holds that the irrigating fluid should be normal

salt solution, and that excision of the edges of the ulcer, or resection of a portion of the bowel containing the ulcer, is uncalled for. Should the intestinal wall be in such bad condition as to render suture of the perforation unsafe or impossible, the involved loop should be pulled out of the abdomen and left there for subsequent resection and anastomosis after the patient has recovered from his fever. He prefers the mattress suture of Halsted and advocates the invariable employment of drainage. It is best accomplished by means of wicks of iodoform gauze carried into different parts of the abdominal cavity if there is a general septic peritonitis, with the ends brought out through the abdominal wound. Drainage should be practised in the most dependent portion.

In over fifteen per cent. of the cases diagnosis was incorrect, but in all cases there was found an intraperitoneal condition absolutely requiring operation. The signs upon which Finney places most dependence are sudden acute pain in the abdomen with symptoms of collapse, accompanied by an abrupt fall in the temperature; vomiting is often present. Other symptoms, such as obliteration of liver dulness, gurgling sound on respiration, hiccough, etc., are useful when present. There is as yet no sign pathognomonic of perforation. The examination of the blood, however, promises to be of distinct diagnostic aid in this record. During the course of typhoid fever the number of white corpuscles gradually sinks, reaching its lowest point at about the end of the febrile period; with the development of the inflammatory complication there is a marked increase in the number of leucocytes, and one which takes place under no other known conditions.

Finney states that in the treatment of a case of perforating typhoid ulcer there are three things to be done: (1) Finding and closing perforation; (2) emptying and cleansing the peritoneal cavity; (3) the establishment and maintenance of effective drainage.

The method employed in his three cases seemed to him most satisfactory. The steps of the operation are as follows:

An oblique incision in the right iliac region, as if for appendicitis, long enough to give ample room through which to work, say six inches in length. Find the cæcum, which is always to be recognized by the longitudinal bands. This is the guide to the ileum (or appendix). Then with this as a starting point systematically draw out the coils of

ileum through the abdominal wound. Let an assistant wipe the intestine as it is withdrawn with a gauze sponge wrung out of hot salt solution, and another assistant keep it covered with warm salt sponges or towels. All the infected intestine should be drawn out of the peritoneal cavity, ileum, jejunum, duodenum—if necessary the whole of the small intestine. Then with large gauze abdominal pads and sponges wrung out of hot salt solution, carefully and systematically wipe out the peritoneal cavity until macroscopically clean, paying special attention to the pelvic portion. It is not usually necessary to irrigate with salt solution to do this. Next uncover the intestines and irrigate them thoroughly while outside the abdomen with hot salt solution; then begin to replace them in the inverse order from that in which they were withdrawn, being careful to wipe them dry, and free them thoroughly from flakes of lymph, fecal matter, etc. The worst coil should be the last replaced, and the sutured portion next the abdominal wound; this should be packed about with strips of bismuth gauze, and a strip introduced into the pelvis, if necessary. By packing about the worst or sutured coil of intestine and leaving it superficially placed, you insure good drainage and provide for the escape of extravasated fecal matter, if any such extravasation should take place. Then close the abdominal wound tightly, except a small opening for the gauze drain to come through. If there is much distention the bowels should be moved early and thoroughly by calomel in broken doses, followed by salts, and if necessary a high turpentine and soap-suds enema.

If stimulation is necessary, more reliance is to be placed on hypodermics of strychnine, enemata of several ounces of hot black coffee, and the transfusion into the cellular tissues under the breast of a quart or more of the normal salt solution, than on any other remedies.

Finally, (1) of all the so-called diagnostic signs of perforating typhoid ulcer, most reliance is to be placed upon the development of an attack of severe continued abdominal pain, coupled with nausea and vomiting, and at the same time a marked increase in the number of white blood-corpuscles; (2) the surgical is the only rational treatment of perforating typhoid ulcer; (3) there is no contra-indication to the operation, surgically speaking, save a moribund condition of the patient.

The statements of Monod and Van Verts

correspond closely to those of Finney as far as the historical part of the subject is concerned. In their statistical study, however, they reject a number of cases as not being certainly typhoid. They carefully consider the objections to intervention, finding none of them sufficient to contraindicate operation, not even diagnostic difficulties to which they accord a proper importance. They tabulate twenty-seven cases in which they consider the diagnosis absolutely certain. Of these five recovered, a total mortality of 81.5 per cent. The mortality of expectant treatment from perforation according to Richardson is ninety per cent., of general perforation following typhoid ulcer ninety-five per cent.

The prognosis is, of course, better when perforation comes late in the disease and occurs in the milder forms of the fever, and when the operation is performed promptly. Barring shock, the usual cause of death is peritonitis. In no case did autopsy show a giving way of the bowel at the seat of suture.

As to operative technique, these authors prefer median celiotomy, unless the peritonitis is circumscribed and can be localized by palpation. The extremity of the small intestine is first explored, beginning at the ileo-cæcal valve, continuing upward for about two feet. The ulcer having been found is sutured with catgut without previous freshening; the Lembert stitch is employed. Multiple perforations of a small section of the bowel would indicate section of this loop of intestine, bringing the divided ends into the abdominal incision. If the general peritonitis is present, the abdominal cavity should be washed out with a mild antiseptic fluid. Drainage is accomplished by means of gauze wicks.

The after-treatment is a stimulant one. The patient may be given iron and alcohol, injections of ether and caffeine, and especially subcutaneous or intravenous injections of serum in large doses.

The authors conclude with the statement that the results of surgical intervention in generalized peritonitis consecutive upon intestinal perforation are not encouraging, but are better than the results of more conservative treatment by a small percentage. Thus in the presence of distinct indications of perforation it is the duty of the surgeon to operate promptly, unless the patient is evidently in such a collapsed condition that any intervention will necessarily be immediately fatal.

## Reports on Therapeutic Progress

### *EUCAINE AS A LOCAL ANESTHETIC IN THE SURGERY OF THE THROAT, NOSE, AND EAR.*

HORNE and YEARSLEY, in the *British Medical Journal* of January 16, 1897, give the details of an interesting investigation of this new drug. The solutions used were in three strengths—two, five, and eight per cent. Of these, they found that the two-per-cent. is quite sufficient for anesthetizing the uvula, etc., for laryngoscopy or posterior rhinoscopy, and for aural examinations. In one case seven drops of a warm two-per-cent. solution dropped into the left ear and retained (with the head inclined to the right) for five minutes caused complete anesthesia of the membrana tympani lasting nearly twenty minutes. Another man, who was most intolerant of laryngoscopy, permitted a complete examination. In the latter case the eight-per-cent. solution was first used, but on the next occasion the two-per-cent. was found sufficient, as also for two other cases of posterior rhinoscopy. The five- or eight-per-cent. solutions have been used for operative procedures on nose, throat, and ear; and although in one case an aural furuncle was incised without pain under the five-per-cent., and in four other cases the same solution sufficiently anesthetized the membrana tympani to permit of myringotomy, it was generally found that for all operative measures on throat, nose or ear the eight-per-cent. solution was the more reliable. Furthermore, eucaine being in their experience (so far) devoid of unpleasant after-effects, it is of advantage to use the stronger solution. In the first case an attempt was made to cauterize an inferior turbinate body under a two-per-cent. solution, thus obtaining their only unsatisfactory result, the case requiring the five-per-cent. before proceeding. They recommend for the ear, warm instillation retained from five to eight minutes by inclining the head to the opposite side; for the nose, either simple swabbing, or the insertion of a pledget of cotton-wool soaked in eucaine for five to ten minutes; for the throat, simple swabbing with a pledget of cotton-wool. On no occasion was eucaine applied by means of a spray.

The authors have found that the anesthesia is slightly slower in onset than that of cocaine, and that five to ten minutes must elapse before the cases were ready for operation. When established the anesthesia is fully equal

to that of cocaine, and in this the writers' opinion is endorsed by the patients who had previously experienced the latter. The duration of the anesthesia is from ten to twenty minutes, fifteen minutes being the most usual time. In the extent of the anesthesia they have had no reason for dissatisfaction. They found that when the membrana tympani was anesthetic, the tympanum and ossicular chain were equally so. A pledget of wool passed into the anterior half of the nares rendered the inferior turbinate body anesthetic in its whole extent. Similarly, simple swabbing of the tonsils rendered them anesthetic throughout.

So far their investigations as to the effect of eucaine on the pulse are inconclusive. In many instances the observations must be excluded as unreliable, on account of the mental influences in the patient due to operation. In the few instances, however, in which the observations may be considered reliable, the pulse has remained the same in rate and character throughout. In no instance have they noted any slowing of the pulse. In only three cases have they seen any unpleasant effects upon the circulation following an operation or examination under eucaine, and in each of these there was sufficient reason to otherwise account for the trouble without attributing it to the drug.

Their observations upon the local effects of eucaine on the circulation are at present incomplete, several points having arisen requiring further consideration. They have not, however, found it to cause hyperemia of the turbinate bodies—in fact in several cases it has induced slight ischemia. In two cases it has been noted that a turbinate body which before the application was in contact with the septum was not touching it in any part when anesthesia was established. Of course, any ischemia observed was not to be compared to that caused by cocaine. This is a point upon which they hope to make further observations in the future. In no case has there been the hemorrhage after an operation which so often forms an unpleasant feature of cocaine anesthesia.

They desire to mention an apparent effect upon the salivary secretion. In the first case in which an eight-per-cent. solution was used to anesthetize the uvula for laryngoscopy, a considerable increase of saliva was noted. On another occasion, when a two-per-cent. solution was used, this feature was absent. A similar increased salivation was noted in another case under the two-per-cent. solution.

In another case of posterior rhinoscopy the saliva was not increased. Out of four tonsillotomies, in only one was increased salivation noted. This is an important point for decision by future observation, as its upholding will establish another point of difference from cocaine (which decreases the salivary secretion), and may detract from the usefulness of eucaïne in operations upon the oral cavity.

With the exception of three cases the authors have not noted a single instance of what might be construed as an unpleasant after-effect; the three exceptions have already been alluded to and explained. They allude to six cases as having experienced the effects of the use of cocaine. In the first of these, a female aged fifty-five, the use of cocaine for the removal of a nasal spur had caused such alarming syncope as to necessitate the employment of ether and amyl nitrite. This case has since been three times under eucaïne without the least discomfort. The five remaining cases all declared that, whilst cocaine had caused unpleasant sensations in the mouth and throat (variously described as "contracting," "freezing," and "numbing"), lasting for some hours, eucaïne on the contrary rendered them anesthetic to the operation without causing any after-effect greater than (in one case) an unpleasant taste lasting half an hour.

Several points remain for further experience to decide, but they consider that their results so far justify them in continuing the investigation. Eucaïne cannot, however, wholly replace cocaine, since the effect of the latter in reducing the size of the turbinate bodies gives it a value as an aid to diagnosis which eucaïne does not appear to possess.

#### THE TREATMENT OF PHTHISIS BY GUAIIACOLATE OF PIPERIDINE.

Another treatment for pulmonary tuberculosis has been devised by CHAPLIN and TUNNICLIFFE and reported in the *British Medical Journal* of January 16, 1897. They begin by saying that the success which has attended the treatment of phthisis by creosote and its derivatives, especially in the earlier stages, has led the authors to try a newly synthesized body, piperidine guaiacolate, which not only contains an antiseptic moiety, but also a constituent which possesses a nervine and vascular tonic action. In order to put their results with this substance as succinctly as possible, they divide

their paper into three parts—(1) Chemistry, (2) Pharmacology, (3) Therapeutics.

Piperidine guaiacolate has been prepared by Dr. Schidrowitz, and for its chemistry we are indebted to him. It is a compound formed by the action of piperidine on guaiacol in a suitable solvent, such as benzol or petroleic ether, and it must be regarded as a guaiacolate of piperidine, having the formula  $C_8H_{11}NC_7H_7O_2$ . Its exact chemical composition is still under investigation; it crystallizes in prismatic needles or plates; it is soluble to the extent of 3.5 per cent. in water, and is also easily soluble in most organic solvents; it melts at  $79.81^\circ C.$ ; it is decomposed into its constituents by mineral acids and alkalies. The chemical property which from a pharmaceutical standpoint is most worthy of note is the relative solubility of this salt. This becomes emphasized when the insolubility of the carbonate of guaiacol is borne in mind. The solubility is such that ten grains can be administered in an ounce draught of simple water, or if the specific gravity of the medium be raised by the addition of a little glycerin or mucilage a dose of from twenty to thirty grains can be given.

The pharmacology of the guaiacolate of piperidine resolves itself into the pharmacology of guaiacol and piperidine, for it is into these substances that the salt is decomposed, probably not in the acid medium of the stomach, but in the alkaline one of the duodenum. The reason for this assumption is that large doses (one drachm) can be given without the slightest eructation of guaiacol. The action of guaiacol is too well known to be discussed here; it acts in the intestine as an antiseptic; in the structures through which it is excreted—for example, the respiratory mucous membrane—it acts also as an antiseptic. When hydrochlorate of piperidine, suitably diluted, is injected into the circulation in doses of 0.05 gramme to the kilo of body weight the heart is slowed and the vessels contracted, a considerable rise of blood-pressure taking place. When injected under the skin in doses of from one to two centigrammes to the kilo, an increase in reflex excitability occurs, so that if the drug is pushed convulsions may develop. Thus in suitable doses piperidine must be regarded as a cardio-vascular tonic and spinal stimulant.

During the last three months an inquiry as to the value of piperidine guaiacolate in the treatment of pulmonary tuberculosis has been carried out at the City of London Hospital for

Diseases of the Chest. The patients to whom the drug was given were subjected to close observation, and the effects of the medicine were noted from time to time. In all, fourteen cases were placed under observation, of which eight were out-patients and six in-patients. The duration of the observations varied, but as a general statement it may be said that six weeks was the average. In order to efficiently test the value of the drug cases were chosen more or less haphazard, some being early cases in which improvement might be expected under appropriate treatment, others being more advanced, while yet others were in such a stage as to make it improbable that much good from any form of treatment would accrue. In all cases the dose to begin with was fixed at five grains three times a day, and this was gradually increased until twenty, and in one case twenty-five, grains were given for a dose. So far as could be gathered from questioning patients and personal observation, no unpleasant effects were noticed. All of them stated that the medicine had agreed with them. Pains were taken to ascertain if the drugs produced any gastric or intestinal irritation, but in no case could it be determined that the processes of digestion were in any way interfered with by the medicine. The authors think this worthy of special stress, because experience has so often taught them that when other derivatives of creosote, such as crude guaiacol, are given over a lengthened period, their use has to be discontinued from time to time, owing to the gastric and intestinal disturbances caused by them. But in these cases no such untoward effect appeared.

With regard to the varied symptoms of phthisis it is difficult to say with certainty that the guaiacolate of piperidine had any distinct effect upon them, for in all cases of phthisis it is so frequently found that improved hygienic conditions (good food, rest, and attention), such as residence in a hospital affords, play a large part in the restoration of the patient's health. This much may, however, be said, that in many instances the cough appreciably improved while the treatment was in progress. The temperature was in no case affected adversely by the drug; in most cases it receded to normal. The appetite for the most part was maintained, and very often patients expressed the belief that the medicine improved it; indeed, in some cases it seemed that it had a markedly good effect upon the appetite. Some patients

gained in weight while the treatment was going on, and in two instances it was thought that more flesh was put on than would have been the case had ordinary remedies been tried. The expectoration in most cases decreased while the drug was being taken. Among the out-patients especially there was a general improvement in strength and vitality. In the case of out-patients it must be remembered that improved hygienic conditions do not come into operation to the advantage of the patient as they do in in-patient practice.

Coming now to speak of the changes noted in the physical signs, it must be admitted that discussion of this subject is full of difficulty, for it so often happens that, although considerable improvement takes place in the general condition of the patient, yet no marked change occurs in the physical signs. Some of the cases (out-patients) whose condition was found to be improving were examined week by week to see if any change could be found in the physical signs. Consolidation and excavation were of course unaffected, but in not a few instances the lungs were noticed to become drier with less moist crepitant râles. This change was attributed to the fact that the area of simple inflammation around the tuberculous infiltration itself had passed from an active to a more quiescent condition. It must be admitted, however, that the same improvement in physical signs could not be seen in most of the cases under treatment as in-patients. Two out-patients considered that the medicine relieved their dyspnea, and to judge from the lung signs, which were improving rapidly under the treatment, it might very well be the case.

In stating the effects of any new drug upon a given disease the physician must always guard himself against "overenthusiasm;" so often it happens that a new medicine has been reputed to be successful in some affection, and upon fuller trial its effects are found to be trifling, or even *nil*. Of piperidine guaiacolate it may be generally stated:

1. That experience has shown that it is a perfectly safe drug in doses from five to thirty grains three times a day.
2. That it causes no unpleasant effects.
3. That it is exceedingly well borne by the stomach, and in this respect it is equal to any other derivative of creosote.
4. That patients while under its influence improved in appetite and general strength.

### A PRESCRIPTION FOR BLEPHARITIS.

The *Revue de Thérapeutique Médico-Chirurgicale* of January 15, 1897, states that LAM-DOLDT employs the following ointment:

- ℞ Neutral acetate of lead, 2 grains;  
Hydrochlorate of cocaine, 3 grains;  
White vaselin, 45 grains.

This ointment is to be applied to the edges of the inflamed lid.

### A PRESCRIPTION FOR HOARSENESS OF THE VOICE.

- ℞ Hydrochlorate of morphine, . . .  
Hydrochlorate of cocaine, of each 1-12 grain;  
Tincture of aconite, 2 drops;  
Powdered marshmallow, 3 grains;  
Sugar, a sufficient quantity.

Make into one pastille and take eight or ten such a day.

—*Revue Thérapeutique Médico-Chirurgicale*, Jan. 15, 1897.

### CREOSOTE IN THE TREATMENT OF PLEURO-PERITONEAL TUBERCULOSIS IN CHILDREN.

In the London *Lancet* of January 16, 1897, Professor THOMA writes an interesting article on this important subject. He first emphasizes the fact that peritoneal tuberculosis in children has for several years been treated by laparotomy, and the results are often very good. We have learned also to distinguish the different forms of this disease, so that its diagnosis and treatment are easier than formerly. Laparotomy is no doubt the best and quickest of all methods for dealing with those cases in which the peritoneum is covered with miliary tubercles; but it is always a serious operation and one also which not every medical practitioner is competent to perform. Moreover, the parents of the little patients are usually averse to surgical interference and anxious for the employment of some other means, so that it is not surprising that physicians should welcome a non-surgical treatment of this dangerous illness. In former years general tonics, painting with collodion, and the local application of iodines were principally relied on; but the results were often bad. Ichthyol has been employed of late years; it is certainly a good remedy, and in spite of its disagreeable smell the author has many times used it with satisfactory results in acute inflammations of the peritoneum. It has frequently happened, however, that these various methods were either ineffectual or else so tedious that children were obliged to stay too long in the hospitals.

Not long ago the idea occurred to the writer that in these cases creosote might be advantageously administered in enemata. The first writer who recommended this treatment was Dr. Revillet of Cannes, but he employed it only for the treatment of phthisis; and after him many physicians have had favorable results. Sometimes this substance disagrees with the patients, causing diarrhea and pains in the abdomen, so that it has either to be discontinued or combined with acetum opii ("black drop"), but this adjunct does not always succeed, and is often contra-indicated. Another difficulty is the necessity for the patient's retaining the enemata as long as possible, in order that the creosote may be completely absorbed. With very young children this is hardly possible, but with his two little patients it was very easy. The enema was given each evening when the child was quiet and before it was put to bed. At first the child could not retain the enema more than three or four hours, but after some days it slept well, and on many occasions only a little oil was found in the morning along with the first motion of the bowels. Dr. Revillet directed the enemata to be prepared with water, a small quantity of almond oil, and the yolk of one egg. Recently, however, it has been proposed by a chemist of Grenoble to administer creosote in milk; forty-three drops of creosote are mixed with a quarter of a glass of milk, and water is afterwards added. This method is evidently more simple and has the advantage that the milk is taken by the mouth, for everybody knows the difficulty of feeding an unwilling child. Nevertheless the writer prefers the association of cod-liver oil with creosote. In an interesting memoir presented to the Faculty of Medicine in Geneva, Dr. Loppino, confirming the experimental researches of Professor Schiff, has proved that fat is very well absorbed by the rectum, and that oleaginous injections are highly important agents in combating emaciation and cachectic states. Dr. Loppino has never seen any bad effects resulting from the practice; the best results were obtained in the case of neurasthenic and tuberculous patients, and it is a useful mode of carrying out the treatment by over-feeding introduced by Dr. Weir Mitchell. This circumstance induced the author to try enemata composed of a mixture of cod-liver oil with creosote. At the outset each enema contained 150 grammes (about four ounces) of emulsified oil and 0.5 gramme (eight grains) of creosote, but after from eight to

ten days he gave one gramme of creosote. In the first case the child took in the course of some days 1.5 grammes of creosote; diarrhea ensued, and the enemata had to be discontinued. After the treatment has been continued for some weeks it is a good plan to suspend it for five or six days and begin again. The author has not noticed that the taste of creosote was perceived by the children; their appetite was somewhat impaired at first, but was not lost, and subsequently improved. By this method it is possible to relieve the disorders of the bowels so frequent in this illness. He thinks that the antiseptic action of creosote is valuable against intestinal fermentations; it is not unusual to find constipation alternate with diarrhea in the first stage of tuberculous peritonitis, an important cause of that condition being weak digestion and the slowness or rapidity of the movements of the intestines. The antiseptic action of the mixture of cod-liver oil and creosote is very efficacious against these troubles, and after some days an improvement will be seen. The absorption of the creosote was unquestionable, for on many occasions the urine was dark-colored. It is possible that creosote may have a curative effect on tuberculous deposits.

The first of the author's cases was a boy, eleven years of age, whose father and mother were alive and in good health. One sister of the mother died from tuberculosis some years previously; the child had often been to see her and was kissed by her. In August, 1894, he fell ill with pleurisy on the right side; the attack lasted fifteen days, but he seemed to recover perfectly. In November he suffered from cough; in February, 1895, he lost his appetite, became very weak, suffered from abdominal pains, and went into the hospital on March 1. On admission he was thin and feverish, his evening temperature being 38.5° C. His tongue was thickly coated and he had no appetite, but there was no vomiting. The abdomen was distended, but not very painful; there was retraction of the hypogastrium, but no indication of ascites. Some obstruction was felt on deep palpation, and there was diarrhea. The urine was normal. The patient had a little cough, and on the left side there was rough respiration with egophony; the breath sound was rough and the expiration prolonged at both apices. Milk diet was given, a blister was applied over the left lung, and ichthyol on the abdomen. On March 7 the signs of pleurisy were increased.

An enema containing nine grains of creosote was administered. On the 14th the enema was retained for eight hours and caused no pain. On the 16th an enema containing fifteen grains of creosote was given. The diarrhea had now ceased, and the condition of the left lung was also better. On April 10 slight ascites was recognized, but the abdomen was less distended and more yielding. On the 20th the amount of creosote was raised to eighteen grains, and the patient's state, both general and local, improved. On the 27th slight diarrhea necessitated the temporary discontinuance of the creosote, as the last dose had been too large; but after a few days the treatment was resumed, and on June 25 the patient's general state was very good, the lungs and abdomen being normal. He then went into the country. The author saw him on August 17, and found that the improvement was fully maintained. On October 5 he set out for Cannes in perfectly good health.

The writer's second case was that of a girl, seven years of age, whose father and mother were in good health. In 1890 she suffered from influenza and bronchitis, and frequently from cough since that date. In March, 1895, her strength and appetite failed. On March 26 fever and cough set in, and on the 29th she was admitted into the hospital. She was at that time anemic and thin, and had symptoms of general bronchitis; on the right side there was a harsh breath sound, with bronchophony and signs of slight, dry pleurisy. There were also diarrhea and loss of appetite, but there was no vomiting. The abdomen was distended, with some retraction in the lower part; there were no ascites; the intestines seemed to be matted together. The treatment consisted in the application of ichthyol to the abdomen and the administering of an enema with nine grains of creosote, but after some days the dose was raised to fifteen grains. The symptoms of bronchitis gradually subsided, and on May 30 the abdomen was less distended, but it was necessary to make an application of collodion to it. On July 1 the abdomen was yielding and free from pain, the diarrhea had ceased, the appetite was good, and the general health was excellent. The child weighed twenty kilogrammes (44 pounds), being a gain of three kilogrammes (6½ pounds). She then went home, but returned to the hospital in the month of August, having partaken too freely of fruit, which had caused diarrhea. After some days of ordinary treatment the diar-

rhea ceased, and at the end of September the patient's health was very good.

Of course it is inexpedient to generalize from two cases, especially as these children were not very ill and were treated promptly; but, keeping in mind the comparatively short duration of the treatment and the necessity for preserving the appetite and the digestive functions as unimpaired as possible, it seems that enemata of cod-liver oil and creosote are well tolerated and give good results.

#### FORMALDEHYDE.

In the *Medical Chronicle* for December, 1896, LEECH gives an interesting summary of the therapeutic possibilities of formaldehyde. Formic aldehyde ( $\text{CH}_3\text{O}$ ) is produced when by means of a specially constructed lamp the vapor of methyl alcohol ( $\text{CH}_3\text{OH}$ ) is passed over an incandescent platinum hood or mantle. The following formula represents the reaction:  $\text{CH}_3\text{O} + \text{O} = \text{CH}_3\text{O} + \text{H}_2\text{O}$ . For some time past a solution of formaldehyde in water of a strength of forty per cent. has been on the market under the name of formol or formaline.

Mosso and Paoletti find that formaline has a bacterial action almost equal to that of corrosive sublimate, while it is much less toxic. One part in 20,000 is sufficient to slow the ammoniacal fermentation of urine, and 1 in 4000 inhibits it altogether. Formaline hinders the coagulation of albumen by heat, but hastens the clotting of blood. It has little influence on the frog's heart, unless in solutions over one per cent. in strength. Very small doses, however, are sufficient to raise the blood-pressure and markedly affect respiration. Doses exceeding one cubic centimeter per kilo of body weight quickly cause death; doses of 0.1 cubic centimeter are poisonous if introduced into the circulation; and even smaller doses produce marked symptoms of irritation. A powerful action on the nervous system is shown, resulting in convulsions, analgesia, and lowering of temperature.

Formaldehyde has been found very useful in pathological work for hardening microscopic preparations and museum specimens. Orth has recently pointed out the value of formaline in this connection.

Several observers have experimented with formaldehyde in the disinfection of rooms. Some of the more recent papers are those of Roux, Trillat, Pfuhl, and Hebert. Opinion is divided as to the practical value of formaldehyde for this purpose.

Horton considers formaline particularly suitable for the disinfection of books, as the vapor is not detrimental in any way to them, while it is very rapid in its disinfectant action. The effect produced during the first fifteen minutes is practically as great as that after twenty-four hours' exposure. He found that in a closed space books can be thoroughly disinfected by using one cubic centimeter of commercial formaline to 300 cubic centimeters of air.

Turning to the therapeutic uses of the drug, Schleich found that when a watery solution of gelatin is allowed to dry in formaline vapor the chemical characteristics of the gelatin are altered. It is no longer affected by hot or cold water, nor by acids or alkalies. Animal tissues, however, have the power of breaking up the combination and setting the formaline free. It was also found that when the formaline gelatin, ground to a fine powder and mixed with cultures of various forms of pathogenic bacteria, was introduced into animals the bacteria did not develop, and the wounds healed without trouble.

Schleich states that with this formaline gelatin powder every acute suppuration can be stopped in twenty-four hours, and wounds made to heal aseptically. He has used it in 120 cases of acute suppurative processes, in ninety-three aseptic wounds, four compound fractures, and two deep scalp wounds. The wounds were only cleansed mechanically, and then thoroughly rubbed with the powder. In fresh wounds the powder formed with the blood a quite dry and firm scab in a few hours.

In cases of necrotic masses, in old ulcers, etc., the powder had very little effect, but it was found that it could be digested with a pepsin hydrochloric acid solution (5 parts of pepsin and 0.3 of hydrochloric acid in 100 parts of water). The formaline gelatin powder is dusted on the wound, and then covered with a dressing wet with the pepsin solution, and the digestive process keeps up a continuous supply of formaldehyde vapor for the wound. The powder is made by drying 500 grammes of purified and dissolved gelatin in the vapor of twenty-five drops of formaline.

Foote has recently published a paper giving an account of forty-five cases of suppurative wounds in which he has used Schleich's formaline gelatin. He concludes that formaline has some antiseptic action, but not so great as to render a suppurating wound sterile. It seemed to control the infection for

two days, and if the character of the wound was such that this respite was enough to secure its closure, the result was perfect. If not, then whatever gain was made in the first two or three days was maintained, and the wound went on granulating from that point. This, however, is a distinct advance on the usual treatment. Another point in favor of the formaline gelatin is that it does away with the necessity of drainage. On the whole, Foote thinks the method marks a distinct advance in the treatment of suppuration, giving the most perfect results in those cases where the cellulitis is moderate and the pus abundant.

Alexander considers formaldehyde the "ideal germicide, deodorant, and antizymotic." He has used it in his practice for a year. He quotes De' Buck and Vanderlinden as having used it successfully in one-half per cent. strength for washing hands and instruments, cleansing site of operation, and for rendering infected wounds, cavities and sinuses antiseptic. Formaline does not spoil the edge of the knives, apparently not attacking metal at all. Dr. Alexander uses the pure forty-per cent. formaline very successfully in chancroid and chancre, applying it locally, a single application being sufficient to cause the ulcer to heal rapidly. He found formaline solution a remedy for pruritus vulvæ when other drugs had failed. Four cases of diphtheria were treated with formaline and whiskey. The whiskey was given internally, and the atmosphere of the rooms impregnated with the vapor of formaline, direct application to the throat being also made with the formaline solution. He finds a spray of one-half per cent. valuable in hay fever, and a spray of one-per-cent. solution in whooping-cough. In ten cases of gonorrhea he used a one-half-per-cent. solution, injected three times a day, with satisfactory results; he found the treatment free from the pain or irritation usually caused by the use of sublimate and other solutions.

Howland has treated six cases of gonorrhea with formaline. In every case the gonococcus was found. He started with a five-per-cent. solution, but found this too strong. In the rest of the injections he used a one-half-per-cent. solution. For the first two or three days irrigations of one quart of hot formaline solution were given twice daily; afterwards once daily until the discharge ceased to contain the gonococci. No internal treatment was given except cathartic pills. All highly-seasoned food, alcohol, tea and coffee were

prohibited. The patients were advised to drink two to four quarts of pure water in the twenty-four hours. Dr. Howland noticed peculiar action of the irrigating fluid on the gonococci. They "shriveled up" and lost their form.

De Smet claims good results from the use of formaldehyde in gonorrhea in women. Sixty cases, some very obstinate, were cured. The vulva was washed with a 1:1000 solution, and the vagina douched through a speculum with a strong solution, varying from 2:1000 to 5:1000. If the uterine cavity and cervical canal were involved, some of the same solution was injected. When there is laceration of the cervix, tampons soaked in 1:1000 solution of formaldehyde are left for two or three hours in the vagina. When fungous endometritis is present the curette must be applied first. The applications give rise to no pain, and may be used daily, or every second day.

Lamarque has used formol in one-per-cent. solution for washing out the bladder and urethra, and in five-per-cent. solution for instillation. In acute gonorrhea and in gonorrheal cystitis he has not had encouraging results. In chronic gonorrhea they have been better. He considers this treatment most successful in cases of tubercular cystitis. The only disadvantage is the pain caused by the drug, which, however, though intense, quickly ceases.

In ophthalmic practice formaldehyde has been used for some time. Valude, in May, 1893, made a communication on the subject to the Société Française d'Ophtalmologie.

Burnett has obtained excellent results in infecting ulcers of the cornea and in purulent conjunctivitis. Corneal ulcers may be touched with a solution of 1:200 or 1:500 every day. For general use as an antiseptic collyrium, a strength of 1:1000 or 1:2000 may be used, though the stronger of these sometimes causes a slight burning sensation.

Davidson finds one part of formaline in 2000 or 3000 of water the most serviceable strength of solution. When he tried it first in hypopyon ulcers, it was dropped into the affected eye three or four times daily, and it seemed of very little use, but on applying it freely every hour it acted very effectually. In abrasions of the cornea and in corneal ulcers, Dr. Davidson believes formaline will be of great value if applied freely and often.

Dr. Stephenson has found a solution of 1:2000 of service in muco-purulent and follicular inflammations of the conjunctiva, when applied thrice a day to the everted lids. In

trachoma it seems to have the power of reducing the amount of secretion.

Solis-Cohen has during the past year seen such good results in the treatment of tuberculosis of the larynx, alike in infiltrative, ulcerative, and vegetative cases, by means of formic aldehyde solutions that he is tempted to believe that in this agent we have a means of treatment superior to any other that he has ever used. He uses the commercial formaline, diluting it to the strength required, which ranges from one-half to four per cent. of formic aldehyde—that is, from one to ten per cent. of the commercial formaline, which contains 0.40 per cent. of formaldehyde. Before making the applications the parts should be thoroughly cocainized, otherwise the application to the mucous membranes causes an intense burning, stinging, and even strangling sensation.

The mode of application is similar to that employed with lactic acid. The parts are thoroughly rubbed with the formaldehyde solution after previous cleansing and cocainization. Beginning with the weakest solution, the strength is increased up to ten per cent. of the commercial formaline, which corresponds to four per cent. of pure formaldehyde. This is the strongest solution he has found it necessary to employ.

Pottevin has tried formic aldehyde for ringworm. The hair having been cut short, and the scalp cleansed, a compress of cotton-wool soaked in a two-per-cent. solution of formic aldehyde was applied to the affected parts, or, better still, to the whole scalp. The whole was then covered with an india-rubber cap, or piece of oiled silk, and left on for twenty-four hours, when a fresh application was made.

The results were not encouraging, as in most cases the remedy did not effect a cure. However, according to an abstract in the *Cincinnati Lancet-Clinic* of November 7, 1896, forty cases of ringworm of the scalp, in hospital out-patients, were treated by formaline applications. The preparation used was formaline in full forty-per-cent. strength, which was vigorously rubbed in with a brush or mop for ten minutes, the hair having been shaved round the patches. The application was repeated every other day on four occasions, and then entirely discontinued. Of the forty cases, only five required repainting from non-eradication of the disease. Microscopical examination was always made before commencing treatment, and the presence of the trichophyton verified.

#### IRITIS AND ITS TREATMENT.

In the *Medical News* of January 9, 1897, Dr. L. F. LOVE points out that the treatment of iritis has progressed but little since the early days of ophthalmology, and for the simple reason that if adopted early the old-fashioned treatment is eminently satisfactory. As in the days of our fathers, it consists essentially in the free exhibition of mercury, of local sedatives and derivatives, and in the free use of atropine. Mercury is best administered by inunction, the system thus rapidly coming under its influence. It should be remembered that the general condition of those attacked by iritis is usually poor, that not rarely the stomach is irritable, and the digestion impaired. Internal medication should therefore be avoided as much as possible, except so far as is useful to build up the system and correct disorders of digestion. The use of mercury should be pushed to the point of tolerance. "Gently touch the gums" is the good old rule, which is probably not very far wrong. Iodide of potassium is of little use in the earlier stages of the disease, but must be used after the inflammatory stages have passed, and when the mercury has been pushed almost to the point of salivation. If, unfortunately, your patient should object to inunctions, then some other form of mercury than the ointment must be used—the protiodide or bichloride internally, or better still the subconjunctival injections as used by Abadie.

Local treatment to reduce the inflammation is very efficacious. Love usually employs the Heurtelpe or Swedish leech applied to the temples. Hot-water fomentations applied to the eyeball are useful in allaying pain, and possibly in lessening the congestion, and should be freely used at frequent intervals and as hot as can be borne. A boric acid solution should also be employed.

But the chief treatment is the use of atropine, which should be administered both early and late, and in sufficient strength to dilate the pupil thoroughly, and at such frequent intervals as to maintain the dilatation. In the early stages the use of a solution of four grains to the ounce of the sulphate of atropine applied every four hours, or even more frequently, is necessary to bring about this result. The writer has found good effects from combining cocaine with the atropine in the earlier stages; it lessens the pain and aids in the more rapid dilatation of the pupil. After full dilatation has been obtained the cocaine may be dropped, but the use of

atropine until all inflammation of the iris has disappeared is absolutely imperative. In uncomplicated cases which are seen at an early stage the progress is very favorable. With neglected cases complications are very liable to occur. The most simple is posterior synechia, which is altogether too frequently seen in eye-clinics, but it is unnecessary at this time to more than refer to the fact that most serious complications are more liable to follow neglect or maltreatment.

The writer has been greatly struck by the tolerance of mercury evident in many cases of iritis. He has seen numbers of cases which, as far as he could determine, were non-syphilitic, which bore readily the absorption of two to three drachms daily of mercurial ointment, for weeks and even months, with no symptoms of pyralization; the mercury was continued until the eye whitened and the evidence of deep injection lessened. In these cases mercury acted as a powerful tonic, the general health improving even more rapidly when the inflammation subsided; and it is in these cases that the most successful results are seen. The author has already referred to the necessity of attending to the general health in many patients. As the majority of cases of iritis occur in patients whose systems have been run down by the presence of syphilitic or other poisons, the Turkish bath is especially useful, and tonic treatment should never be neglected.

In conclusion, he impresses upon the profession the facts that iritis is readily recognizable and is a most tractable disease if taken in time. The treatment is simple and effective, and there is no reason why nearly every case of iritis coming under competent care should not make a good recovery.

#### *STENOCARDIA (ANGINA PECTORIS).*

H. N. HEINEMAN of New York writes on this topic in the *Medical News* of January 9, 1897. After discussing the etiological and other factors in these cases he recalls the fact that a great many attacks are excited by the influence of cold. The avoidance of cold water, and even of tepid water, to any large surface of the body on account of the succeeding chill must be advised. Such patients must wash their bodies one part at a time, and have that part well dried and covered before proceeding to the next. Even the keeping of the hands well gloved, maintaining warm feet, protecting the mouth and nose

from the sweeping cold wind or air, are precautions that will save the patient from many an attack. The regulation of the patient's life and habits come under this category. Avoidance of mental worry and emotion, of overexertion, and even needless exertion at times, is imperative. The patient must walk with deliberation, and the combination of walking and talking may be too great a strain for the heart until it is improved by general treatment. Tobacco should be absolutely interdicted, and all spirituous liquors as well. In persons who have always taken wine, a small quantity of a light Moselle or claret, preferably Moselle, may be taken diluted at dinner or, exceptionally, if the patient feels weak and in need of it. Overindulgence in food must be guarded against. If the patient has the prodromal symptoms of an attack, the seeking of shelter, of a warm room, of warmth to the surface, or resting lying down, may ward off an attack.

The general treatment must have two objects: first, the improvement of the heart and blood-vessels; and second, the relief of engorgement in the internal viscera and capillaries.

For the improvement of the heart and blood-vessels, the use of potassium or sodium iodide in from three- to five-grain doses kept up for months is an old remedial agent of a certain, though not always satisfactory, value. The treatment by saline baths and by the Schott method of exercises has a most potent effect in improving the condition of the cardiac muscle and vessels, and appears to have a direct effect in making the attacks less numerous and severe, and even in causing them to cease during a period of months or years.

The exercises with resistance, or Schott movements, should be carried out in the way indicated by the writer in a previous paper read before the general meeting of the New York Academy of Medicine. The movements are made in such a manner that the attendant can easily resist or hinder the movement, and the patient in seeking to complete the movement must overcome the resistance of the attendant. The movements must be made with especial care and caution in these cases, and the resistance at the outset must be at a minimum.

The artificial saline baths should contain from one to three per cent. of salt, and from one-fourth to one per cent. of chloride of calcium, and should gradually be strengthened by the addition of carbonic acid. By a

process now in the last stages of completion it will be possible to prepare the saline effervescent and saline effervescent flowing baths by means of a simple apparatus, so that the carbonic acid will be intimately mixed with the water.

For the relief of visceral and capillary engorgement we may resort to medicinal agents. Although the baths and exercises do this to a marked extent, the administration of a half-grain of calomel (well triturated) thrice weekly at bedtime, succeeded the next morning by a dose of Carlsbad sprudel salts, adds materially to the effect.

After the visceral engorgement has been much relieved, we can now use our nitrites, and in some cases nitroglycerin; for until visceral congestion is relieved it is only playing "hide and-seek" to try to relieve the capillaries, which are immediately clogged again by the nearest congested viscus. Having accomplished this, we now find the cardiac tonics—sparteine, strophanthus, strychnine, valerian, and in suitable cases digitalis—of the greatest utility.

The general tendency to anemia and defective oxygenation must never be lost sight of, and general tonics, including the use of oxygen gas, as recommended by A. H. Smith, will be of excellent service.

The treatment of the attack includes the use of nitrite of amyl in from three- to five-drop doses poured upon a handkerchief, or taken from a glass pearl in similar manner and inhaled.

The use of nitroglycerin in  $\frac{1}{16}$ -grain doses is of less rapid efficacy. It may be repeated once in three or four hours, or even longer intervals. In a severe attack it may be given at half-hour intervals, but should be given guardedly. In some patients the effect of nitroglycerin is immediate, in others very slow. Hypodermic injections of morphine, with or without atropine, is often of great service.

The use of ether or chloroform, with or without valerian internally, relieves moderate spasm, and is somewhat stimulating. Local counter-irritation, by issue, sinapism, or blister over the præcordium, or the actual cautery over the præcordium, or applied over the hepatic region in some cases, and the application of electricity, may be resorted to. Sometimes the local application of the hot-water bag is of service. Exercises given with extreme caution have in the writer's own hands sometimes given some relief to the acute symptoms.

To recapitulate, he wishes to emphasize that the treatment should not be haphazard, but systematic, if we would accomplish anything; and considering the suffering entailed by this disease and the danger involved, such attention upon our part is essential and called for.

First, we must remove exciting causes of every kind, and next relieve the visceral engorgement that has long existed because the heart was too weak and the vessels not elastic enough to keep up proper venous circulation; and having gotten rid of the *vis a tergo*, we relieve the capillaries by appropriate remedies and coincidentally stimulate the heart, which can now act better because its capillary embargo has been raised. The success of the treatment depends upon the following out of the sequence just suggested. The comfort to be guaranteed to the patient, and the prolongation of life, are sufficient rewards for patient toil and scientific interest.

---

#### CAJUPUT OIL FOR CROUPOUS PNEUMONIA.

In the *Indian Medical Gazette* for December, 1896, SINHA reports that he has treated eighteen cases of pneumonia with oil of cajuput, with great success. He gives it in the dose of five drops in emulsion every four or five hours.

We note, however, that in several instances he continued its use with *nux vomica* and camphor and other drugs, which may have had much to do with the good effects produced.

---

#### A NOTE ON DECOMPOSITION OF CHLOROFORM AND SICKNESS.

In the London *Lancet* of January 23, 1897, NEWMAN and RAMSAY report the following interesting facts concerning the decomposition of chloroform and the development of illness subsequent to its use.

Early in the history of chloroform it was noticed that the agent had a tendency to undergo spontaneous decomposition on exposure to air and light, and although within recent years great care has been taken by manufacturers of the drug to produce as pure an article as possible, nevertheless the fact remains that chloroform is not stable and rapidly deteriorates as an anesthetic. When freshly distilled chloroform is administered the vapor is easily inhaled, having a sweetish and not unpleasant taste and odor. It produces little or

no irritation in the air passages, little excitement of the patient is observed, and if the agent is carefully given sickness, fainting, and irregularity of the pulse and respiration seldom occur during its administration. But if chloroform is kept in a bottle containing air, exposed even to feeble light, changes are produced in the drug which render it less suitable as an anesthetic. The change is due to the formation of carbonyl chloride and hydrogen chloride, according to the equation  $\text{CHCl}_3 + \text{O} = \text{HCl} + \text{COCl}_2$ . These substances render the vapor slightly pungent in odor, and on inhalation it produces irritation in the air passages. The period of excitement of the patient is more marked, and the liability to sickness during and after anesthesia is greater.

During the last six months the effects of freshly distilled chloroform and of chloroform supplied in the ordinary way have been contrasted, greatly to the advantage of the former. It has been found, however, that distillation is not necessary, as by shaking the chloroform with slaked lime, and filtering, the irritating products of decomposition are eliminated, as indeed theory would predict; for the hydrochloric acid is of course at once acted on by the lime, giving calcium chloride and water, and the carbonyl chloride, to the presence of which the sickness is probably to be ascribed, is resolved into carbonate and chloride of calcium, thus  $\text{COCl}_2 + \text{Ca(OH)}_2 = \text{CaCO}_3 + \text{CaCl}_2$ . In illustration the three following cases may be mentioned:

CASE I.—A man was operated upon on three occasions. For the first two the chloroform had been given in the wards for not more than ten days, and was kept in a well-stoppered bottle away from direct light; but the bottle contained some air. Each operation lasted fully an hour, and on both occasions the pulse became very irregular and feeble, so as to necessitate artificial respiration. While recovering from the effect of the chloroform he was very sick, and the sickness continued for two days after the first operation, and for three days after the second. The third operation lasted for one and a half hours. Chloroform which had been kept with slaked lime in it and filtered before use was employed. The patient, although much feebler through disease, remained well during the operation, and there was no sickness for twelve hours, when he suddenly became sick, but this passed off in a short time.

CASE II.—A woman had been under chloroform four times, and she was invariably very

sick while coming out and afterwards, the sickness lasting for twenty-four hours or more. When chloroform treated with lime was used, on coming out of the anesthetic sickness occurred for a few minutes only.

CASE III.—A man was under chloroform four times. On the first and third chloroform as supplied by the druggist was used, and it was not more than twelve days old. After both operations there was severe sickness, lasting for thirty-six hours. On the second and fourth administrations freshly distilled chloroform was employed, with no sickness.

As a matter of experience it was found that freshly prepared chloroform is more reliable as an anesthetic, and is less likely to produce sickness during or after administration, and the risks of anesthesia are probably increased by the decomposition of chloroform when kept for any considerable time exposed to air and light. Even with fresh chloroform sickness may occur if the patient is allowed to come out during the operation, but the quantity of acrid mucus is very small in amount as compared with what is seen when older chloroform is given. Perfectly pure chloroform is said to be a much less stable body than chloroform containing alcohol. As an instance of the instability of pure chloroform it may be mentioned that a sample left in a half-full stoppered bottle from July till October, 1896, smelt as pungent as hydrochloric acid, gave with baryta water a copious precipitate of carbonate, and was absolutely irrespirable.

#### THE ACTION OF THE SUPRARENAL GLANDS.

An excellent summary of this subject is made by STOCKMAN in the *Edinburgh Medical Journal* for February, 1897. As he states experimental researches on animals have shown that the subcutaneous and intravenous administration of suprarenal extract produces remarkable physiological effects. The active substance is contained in the medullary portion of the gland, and the activity of the extract has been shown by Fränkel (*Wiener Medicinische Blätter*, 1896) to run parallel with the distinctness of certain color reactions (e.g., a green with ferric chloride), which are due to a substance which has not yet been isolated in a pure state. Moore has shown (*Proc. Physiol. Soc.*, London, 1895) that the active constituent is neither a proteid nor a carbohydrate, that it is not affected by acids nor by boiling for some minutes, but is de-

stroyed by alkalies, reducing agents, and prolonged boiling. It is not altered by artificial peptic digestion, and therefore, according to Oliver and Schäfer, preparations of the gland may be rationally given by the stomach, an opinion which has now been confirmed by therapeutical results. The active principle is readily extracted by water, glycerin, and weak alcohol, and is apparently a compound of pyrocatechin, as this body has been obtained from it by chemical decomposition (Mühlmann, *Deutsche Med. Wochenschr.*, Leipzig, 1896, No. 26). Oliver and Schäfer in an elaborate research (*Journal of Physiology*, Cambridge and London, vol. xviii, pp. 230-276) have shown that extracts made from the suprarenal glands of the calf, sheep, guinea-pig, cat, dog and man have a similar action. Diseased glands from cases of Addison's disease were found by them to be inert. The doses used intravenously were equal to from one-fourth to three grains of the fresh gland, and the former dose exercised a marked physiological effect on the circulation of dogs. The active principle, whatever it is, must therefore be recognized as an exceedingly powerful body, if we reflect that of this one fourth of a grain about eighty per cent is water, and another very large proportion must consist of the proteids, etc., of the gland substance.

These authors found that the subcutaneous injection of large doses of extract (equal to fifteen grains of fresh gland) in dogs only produced a temporary stimulation of the heart and respiration, while the temperature was slightly raised. Rabbits died after smaller doses with symptoms of respiratory failure. They found that after intravenous injection of small doses the blood-pressure was raised to a remarkable degree, and this they attribute to a marked stimulation of the heart muscle and arterioles. The skeletal muscles were also stimulated, and hence they conclude that one function at least of the gland is to maintain tone in the voluntary and involuntary muscles by means of its secretion. In their opinion this view is strengthened by the fact that removal of the suprarenal bodies causes weakness of the heart and muscular system generally, with great want of tone in the vascular system.

Gottlieb (*Arch. für Exper. Path. und Pharmacol.*, Leipzig, 1896, bd. xxviii) comes to the conclusion that the marked stimulation of the heart and arterioles is probably due to an action on their intrinsic nervous ganglia, rather than to a direct action on the muscu-

lar fibres. He states also, what had been previously observed by Cybulski, that administration of the extract by the mouth or subcutaneously had very little effect on the circulation, compared to what is observed after intravenous injection. The obvious inference is that the active principle is destroyed by the tissues. Previous researches by Pellacani and others had demonstrated that suprarenal extract was very poisonous to all kinds of animals, while Brown-Sequard, Tizzoni and others had shown by ablation experiments that the glands were essential to life, and that excision is followed sooner or later (four to thirty-six months) by emaciation, muscular weakness, and death. Pigmentation was observed in animals which died slowly, and the whole symptoms are analogous to those of Addison's disease in man.

A very complete critical summary of our knowledge of the suprarenal bodies and their relation to Addison's disease has been given by H. D. Rolleston in the Goulstonian Lectures for 1895 (*British Medical Journal*, London, 1895, vol. i), in which, after a very full discussion, much too long to be reproduced here, he concludes that Addison's disease may theoretically be dependent on (1) suprarenal inadequacy, or (2) chronic toxemia, due to non-removal from the blood by the suprarenal glands of toxic products of tissue metabolism. He is of opinion that the first view is alone tenable in the light of our present knowledge, and that the glands in Addison's disease fail to secrete a substance which is essential to health and life. What the exact function of their secretion may be is not yet known—whether its absence leads to a toxic condition of the blood which poisons the other tissues, or whether the want of it leads directly to an atonic state of the whole muscular system, are questions which for the present must be left open. These and many other important points, such as the origin of the pigment, are still very obscure, and further investigation may of course greatly modify our present opinions.

The treatment of Addison's disease by suprarenal glands and preparations has aroused considerable interest. Oliver has treated two cases with suprarenal preparations given by the mouth ("Pulse Gauging," 1895). He used pills in which one grain of dried extract corresponded to fifteen grains of the fresh gland, and an alcoholic solution of which one minim equaled one grain of gland. The results in both cases were encouraging: there was a gain in weight, lessening of pig-

mentation, and disappearance of nausea and anorexia. Rolleston states that a case of his has also greatly improved in much the same directions. He thinks that "a dose equal to forty-five grains of the original gland, spread over the twenty-four hours, is certainly not too much."

Stockton (*Medical News*, Philadelphia, 1895) gave two suprarenal capsules of the sheep daily raw, and after three months there was a very distinct improvement in the bronzing and in the general condition of his patient.

Lloyd Jones reports a case (*British Medical Journal*, London, 1895, vol. ii) in which suprarenal tabloids and extract were given, and where after four months' treatment "the excessive pigmentation has quite disappeared, and she appears to be practically well."

Dr. Sansom reports a doubtful case in which arsenic did no good, while the man improved greatly on two tabloids of suprarenal gland twice daily. When the treatment was discontinued the patient relapsed. In none of these cases is mention made of the probable lesion in the suprarenal glands.

M'Lauthlin (*Medical News*, Philadelphia, 1895) treated a case unsuccessfully with an extract, and after death fibro-caseous disease of the suprarenal bodies was found.

Sir Dyce Duckworth ("Twentieth Century Practice of Medicine") states that Sir Thomas Grainger Stewart has treated a case without any beneficial results.

The writer has had an opportunity of treating two cases of Addison's disease with suprarenal bodies. In one of these no improvement whatever occurred, and post-mortem tubercular changes in the lungs and suprarenal capsules were found. In the other, where the bronzing and general asthenia followed an injury to the back, marked improvement in the color of the skin and in the general condition took place in two months, when three and then six raw sheep's capsules were given daily. The improvement has now been maintained for twenty months under the constant administration of an extract. When it is omitted the patient relapses, but he is now able to follow his ordinary occupation.

Byrom Bramwell (*British Medical Journal*, London, 1897, vol. i) gives the details of a case in which after death the suprarenal bodies were found to be replaced by masses of fat. He was treated twice weekly by the hypodermic injection of a dose of extract, equal to a quarter of a rabbit's suprarenal capsule, and later a smaller dose was given

every second day by the mouth. Marked improvement followed.

It may be noted that as yet no case has been reported in which complete and permanent recovery has taken place, although the subjective and objective symptoms are often very materially improved. Cases of fibro-caseous degeneration seem to derive no benefit, while those in which atrophy of the glands may reasonably be diagnosed give much better results.

Oliver (*British Medical Journal*, London, 1895, vol. ii), from his observations of the effects of suprarenal extract in contracting arterioles and from clinical observation, suggests that the extract may be usefully given in anemia, cyclic albuminuria, diabetes mellitus and insipidus, exophthalmic goitre, heart disease, and capillary hemorrhage.

#### THE TREATMENT OF CHILBLAINS.

M. GEORGE THIBIERGE contributes a long article on this subject to the *Journal des Praticiens* of January 9, of which the following is the substance:

Chilblains, he says, are always painful in a more or less marked degree; their development is preceded by pruritus and a sensation of heat and of pricking; after they have become established they are also accompanied by the same sensations, which are tolerable when the diseased parts are exposed to cold, and extremely painful when subjected to heat; changes from cold to heat, and frequently rest in bed, arouse and increase their intensity; this symptom is of great diagnostic value. Even simple pressure is extremely painful, however slight the lesions. To this may be added tumefactions and ulcerations, thus rendering chilblains veritable infirmities.

Chilblains may be followed by a general tumefaction of the regions attacked, which is the result of local asphyxia even more than of the chilblains themselves. In the hands this tumefaction gives an entirely peculiar sausage-like aspect to the fingers, somewhat like that resulting from acromegaly.

Another consequence, still more rare, of chilblains is the production of localized and persistent vascular dilatations, true acquired capillary angiomas, on which there are small papillomata resembling warts.

The erythematous congestion of the hands, or rather of the extremities, which in certain subjects appears when cold weather sets in, and is one of the forms of what is known as

Raynaud's disease, is an important predisposing cause. In young people the insufficiency of peripheral circulation which it causes should be attributed especially to the slight paralysis of the vaso-motor system; in older persons it arises principally from atheroma, which impedes the local circulation, the effects of which are further marked by weakness of the myocardium and by the blood dyscrasia depending upon senile interstitial nephritis. It must be noted, moreover, that this asphyxia of the extremities is not necessarily followed by chilblains, and that they may develop in non-asphyxiated regions.

Defective or insufficient alimentation singularly facilitates the development of chilblains; inactivity also helps their development; cold, aided by defective conditions of circulation and of the functions of the economy, is the cause of chilblains, and it exerts still greater effects when the skin is wet or not properly dried, or when it is suddenly succeeded by heat. Chilblains may often be prevented if the parts which have been exposed to the cold are slowly and progressively warmed; the vascular dilatation which provokes the too rapid return of heat is followed by a paralysis of the blood-vessels, which shows itself sometimes by erythema and sometimes by gangrene; this mechanism intervenes not only in the production of chilblains, but in that of the functional troubles which accompany them.

The conditions which predispose to the development of chilblains show what importance a general tonic medication should have in their treatment and their prophylaxis. Cod-liver oil, preparations of iodine, iron iodide, and arsenic are indicated in all cases, and their regular and prolonged employment often leads to the attenuation, in a very great proportion, of the tendency in certain subjects to chilblains.

Quinine sulphate often renders great service in an affection in which the circulatory troubles of the extremities play an indisputable part. M. Besnier recommended the prolonged employment of this medicament, with which he occasionally obtained unhopd-for results. M. Brocq found good results from the association of quinine sulphate and of ergotin in doses of from 0.75 of a grain to three grains with powdered digitalis (from 0.2 to 0.3 of a grain) and the extract of belladonna (from 0.03 to 0.06 of a grain) in the form of pills, the employment of which was prolonged during the entire winter.

Inhalations of oxygen, which accelerate nutritive changes and often give remarkable results in asphyxia of the extremities, are indicated in subjects in whom the sluggish condition of circulation predisposes them to chilblains.

Regular exercise, walking, gymnastics, cold affusions and general stimulating lotions are also extremely useful prophylactic means in the majority of subjects in whom a former experience has demonstrated their tendency to the development of this infirmity.

The part which local causes, and particularly the direct action of thermic agents, play in the development of chilblains furnishes prophylactic indications which should not be neglected. The hands should be covered with thick and sufficiently warm gloves, but rough woolen gloves should be avoided. They, like the feet, should be washed in warm water (not in cold) and carefully dried on a towel (never before a fire), and then powdered with starch or talc in order to remove every trace of dampness. The hands should not be allowed to remain too long in cold or soapy water. Shoes and stockings should be comfortably large, as the pressure of the foot on the shoe favors the action of the cold; they should be thick enough to protect the feet against the action of the cold, especially when there is snow on the ground. If sweating accompanies the chilblains, repeated foot-baths must be resorted to and the parts powdered with starch or talc to which has been added from one to two per cent. of salicylic acid.

Foot-stoves should be absolutely proscribed, and the feet should never be dried or warmed by a fire; if they are cold the best way to warm them is to rub them with a slightly warmed piece of flannel.

Foot-baths containing small quantities of astringent decoctions of walnut leaves, of ash leaves, of eucalyptus leaves, of oak bark, etc., of from five to six minutes' duration, constitute a very useful means of preventing frost-bites by increasing the resistance of the skin.

The employment of camphorated soap, or of a camphorated ointment (seventy-five grains of camphor and an ounce of vaselin), applied at night has often seemed efficacious to hinder the development of chilblains in subjects predisposed to them. The same results have been obtained by gentle friction with a piece of flannel saturated in strong spirit of camphor, according to M. Besnier.

If the lesions are not very intense, and

characterized only by red patches not very extensive and scarcely prominent, the preceding modes of treatment are indicated, particularly the local astringent baths, the camphorated preparations, and the absorbent powders. But if the lesions are pronounced, the patches large and prominent, these modes of treatment must be associated with or replaced by other topical agents, ointments, or collodion. The substances which are incorporated in them are intended to increase the consistence of the ointment, such as zinc oxide; or to allay the pruritus, such as opiates, carbolic acid, and menthol; or they are endowed with resolvent qualities, such as lead salts, of which the most commonly used is lead subacetate, which is anticonsmatic.

When the lesions are constituted by red elements, with little or no infiltration of the skin, zinc-oxide ointment such as the following, to which has been added a small quantity of carbolic acid or menthol, will suffice to allay the pruritus and cause the rapid disappearance of the lesions:

- ℞ Zinc oxide, 150 grains;  
Carbolic acid, 8 grains;  
Vaselin,  
Lanolin, of each 225 grains.

M.

Another formula is this:

- ℞ Zinc oxide, 150 grains;  
Menthol, from 3.5 to 4.5 grains;  
Vaselin,  
Lanolin, of each 225 grains.

M.

If the elements are more prominent, more inflamed, the preferable treatment is with an ointment containing lead salts, such as the following:

- ℞ Lead subacetate, 30 grains;  
Carbolic acid, 8 grains;  
Zinc oxide, 225 grains;  
Vaselin,  
Lanolin, of each 300 grains.

M.

Or the following formula may be employed:

- ℞ Lead subacetate, 30 grains;  
Bismuth subnitrate, 90 grains;  
Rousseau's laudanum, 15 grains;  
Vaselin,  
Lanolin,  
Lard, of each 150 grains.

M.

These formulæ may be modified.

Simple elastic collodion, or collodion combined with iodine or salol, or better still the collodion made with acetone, which makes a better covering and does not produce the fissures which occur so frequently after the

use of ordinary collodion, is an excellent protector for the diseased surfaces, and allays the pruritus; but it should never be applied to ulcerating chilblains or to those on which blisters have formed.

The following formula is recommended:

- ℞ Pyroxylin, 45 grains;  
Acetone, 300 grains;  
Ether,  
Alcohol, of each 150 grains;  
Castor oil, 60 grains.

M.

When the chilblains resist these topical applications, ointments containing silver nitrate, or painting with a fifty-per-cent. solution of silver nitrate or with the tincture of iodine, often hastens their resolution; these substances, however, cannot be used on the face, because of the discoloration they cause.

If blisters form they should be opened aseptically and covered with a dressing of vaselin and boric acid, or with freshly prepared Carron oil to which has been added two per cent. of carbolic acid. If these blisters have been ruptured, or the chilblains are ulcerated, after bathing the parts with a weak solution of corrosive sublimate they should be covered with a dressing of vaselin and boric acid or with non-irritating plasters, such as zinc oxide, simple boric acid, and dermatol plasters, or Vidal's red plaster. If the ulcerations do not disappear they should be touched every two days with a silver-nitrate stick, or with tincture of iodine, and dressed with camphorated brandy, with Van Swieten's liquor diluted one-half with water, or with aromatic wine. These dressings should be carefully applied, particularly on the toes and between the fingers, where, according to M. Besnier, it is well to place small tampons of absorbent cotton.—*New York Medical Journal*, Jan. 30, 1897.

#### PRESCRIPTIONS FOR TAPEWORM IN CHILDREN.

- ℞ Peppermint water, 2 ounces;  
Ethereal extract of male-fern, 1½ drachms;  
Essence of turpentine, 15 minims;  
Syrup of orange flowers, 1 ounce.

This is to be taken at one dose. It must be well shaken.

(We regard this dose of ethereal extract of male-fern as being too large).

Or in its place the following prescription may be employed:

- ℞ Syrup of mint, 6 drachms;  
Castor oil, ½ ounce;  
Ethereal extract of male-fern, 30 minims.

Or,

- ℞ Etheral extract of male-fern, 1 drachm;  
Calomel, 6 grains;  
Gelatin or sugar, a sufficient quantity for one dose.

Or,

- ℞ Tamarind pulp, 1 ounce;  
Powdered kamala, 1½ drachms;  
Lemon and sugar, a sufficient quantity to make a confection.

Or,

- ℞ Tincture of kamala, 2½ drachms;  
Syrup of orange flowers, 1 ounce;  
Peppermint water, 2½ ounces.

To be taken at one dose.

After the administration of any one of these prescriptions, unless a purgative is contained in them, from a dessertspoonful to a tablespoonful of castor oil or some senna should be given to remove the poisoned worm.

—*Journal des Praticiens*, Dec. 12, 1896.

#### TAKA-DIASTASE: ITS USE IN CERTAIN FORMS OF DYSPEPSIA AND GOUT.

The *Liverpool Medico-Chirurgical Journal* for January, 1897, contains an article on Taka-Diastase as a digestive ferment written by Dr. WILLIAM ARMSTRONG. He points out that it has become so much a matter of routine to rely upon pepsin for the relief and cure of dyspepsia that the influence of the active principles of the salivary secretion on the process of digestion has been somewhat lost sight of. It is only when cases of acidity, flatulence, etc., are met with which resist the action of digestive ferments of the pepsin group that attention is specially directed to the influence of the primary digestive agent. He has been much interested, during the treatment of a large number of gouty patients, to find that although many of them had for months been deprived of almost all butcher's meat and other nitrogenous foods, the acidity, flatulence, digestive discomfort and general goutiness had gone on much as before.

Considerable light has been thrown on this subject by the success of the so-called "Salisbury" dietary; for under the exclusive use of red meat (aided by hot water drinking when the stomach is empty) many intractable cases of chronic gout and dyspepsia have been speedily and permanently relieved. This fact certainly points to one of two things—either that red meat is not the harmful agent in gout that many have supposed it to be, or, what he regards as more likely, that the admixture of the meat with the carbohydrates interferes with the due digestion of each.

The early loss of the masticating teeth, which we now so often find, the haste with which meals are so frequently taken, and more especially the custom of taking considerable quantities of hot fluids, such as tea, with food, give rise to a tendency to wash the food quickly down the first passages, and so prevent it being thoroughly mixed with the saliva; and thus, as the gastric juice has no converting influence over the starchy elements, they become decomposed, giving off a large quantity of gas and forming amylomptomaines, which are almost if not quite as harmful as those ptomaines formed from nitrogenous foods. The elimination of the starchy elements of the food is, however, a heavy price to pay for relief from the slighter functional symptoms; and it is not until serious disease becomes evident that patients will submit to this somewhat severe and irksome form of dietary, which, as it often causes considerable and rapid loss of weight, is not suitable for a large proportion of the cases met with in daily practice. As is well known, malt extract is a potent starch-converting agent, but the amount of contained sugar makes it a double-edged weapon, and it often does more harm than good in cases of gout and dyspepsia.

Some twelve months ago the writer was induced to give a trial to "Taka-Diastase"—a brown powder, free from odor, with a slight and not unpleasant taste, for which was claimed the power of converting one hundred times its weight of dry starch.

This powder was discovered by Mr. Takamine, a Japanese chemist, who, while studying in Glasgow, became greatly interested in the process of malting, which he came to consider as unduly tedious and costly. On returning to Japan he, with the assistance of Professor Atkinson, of Tokyo University, commenced a very exhaustive series of experiments, with a view to finding a class of plant capable of converting the starch in cereals into sugar, and the sugar into alcohol. He at last found what he required in the fungus of the species *Eurotium oryzae*, belonging to the *Aspergillus* family. This microscopic fungus he cultivated on the flakes of hydrolized wheat bran, and succeeded in separating the diastatic and fermenting properties, so that either could be used without the other.

The writer has given the diastatic powder in doses of from three to five grains in a considerable number of cases, both of amyloseous dyspepsia and of the form of gout which seems

to be caused by that defect, and with excellent results. He has usually given it in powder with or immediately after meals, especially those with which much starchy food is taken; but it can also be given in mixtures, if neutral or slightly alkaline. Flatulence and acidity are greatly diminished, there is much less strain put upon the comparatively weak intestinal digestive processes, and the gouty symptoms are much relieved.

Taka-Diastase has never in the writer's experience caused the slightest discomfort, loss of appetite, or digestive disturbance: the dose is so small, and the drug itself so free from unpleasantness, that patients take it readily.

The subjects of amylaceous dyspepsia should of course masticate their food slowly and completely, and should also avoid the taking of much fluid with meals,—such liquid as is necessary for the bodily processes being taken one hour before food, preferably in the form of hot water, and that required with meals being taken at the end thereof.

The author is convinced that in Taka-Diastase we have at command a remedy of the highest value, which is capable of giving excellent results in many obstinate cases of dyspepsia, auto-poisoning with amylo-poisoning, and the resulting train of symptoms so frequently classed together under the names of latent and suppressed gout.

#### *THE ABUSE OF "ASTRINGENTS" IN THE TREATMENT OF EYE DISEASES.*

EDGAR A. BROWNE in the *Liverpool Medico-Chirurgical Journal* for January, 1897, says that the "astringents" in general use are the sulphates of zinc, alum, and copper, the chloride of zinc, nitrate of silver, and acetate of lead. The absence of sulphate of iron will be noticed from this list; nobody prescribes sulphate of iron for eye diseases, but it is extensively used for general purposes. Nothing could more clearly indicate the capricious and irrational mode in which these remedies have been adopted. Regarding these substances not as astringents but as antiseptics, the zinc sulphate may be regarded as of good general utility. It is popular, common, and cheap—all points in its favor. Against alum he has conceived a dislike—he can scarcely put his reasons in words. When he first joined the staff of the Liverpool Eye and Ear Infirmary, it was the remedy most in use. Seldom a case escaped it at some stage or other of its course. He has a distinct preference for the

copper sulphate in the muco-purulent and purulent conjunctivitis that runs through schools, and in all early stages of trachoma. For mild cases of ophthalmia neonatorum the chloride of zinc has been used for many years. It will be remembered that it was one of the earliest antiseptics. Surgeons used to pump it freely into operation wounds; and it began to be used empirically, and not as an antiseptic. The true nature of ophthalmia neonatorum was not suspected. Though there are better, it may still be regarded as an excellent remedy, belonging to the most valuable class of chlorine compounds, whence come many of our best disinfectants. It has the disadvantage of being extremely irritating. If used at all too strong it causes the lids to swell, and gives rise to a copious discharge of mucus. This can be verified on the healthy eye.

The writer has already referred to the discharge of mucus as disadvantageous. It is so because it forms a habitat peculiarly suited for germ culture. An antiseptic that gives rise to mucus partially defeats its own object. It is in the removal of this favorable soil that lotions of boracic acid or borax prove useful. They act as detergents, their antiseptic power being feeble in the extreme.

Nitrate of silver cannot be dispensed with in the routine treatment of severe purulent ophthalmia in the adult or the new born. The conjunctiva will stand a good deal of the nitrate, but the cornea is extremely intolerant of it. If the epithelium is abraded, or ulceration occurs, it gives rise to white opacities. For reasons which cannot conveniently be detailed here, it seems to exercise an unfavorable influence on corneal ulceration. If used, too much care cannot be exercised in applying it religiously to the whole surface of the inflamed conjunctiva. Generally it is flooded on the cornea where it is not wanted, and it never reaches the superior conjunctival cul-de-sac where it is essential.

A few words on antiseptics which have no spurious reputation as "antiseptics" to create confusion: The perchloride of mercury has a good clinical and laboratory reputation; it has the advantage of being cheap and readily procurable, a great point in the treatment of common and wide-spread diseases; it may be used in solutions of from 1 to 5000 to 1 to 10,000 in all forms of ophthalmia, and as a precautionary lotion; it has the disadvantage of being irritating, and occasionally giving rise to permanent white opacities of the cornea. This is especially the case when cocaine is used, and many surgeons are aware

of the drawback in cataract extractions. The writer has seen two cases of ophthalmia neonatorum, where the cornea was covered with dense dotted white opacities, due to the action of the perchloride.

A better remedy is the oxycyanide of mercury, which may be used in solutions of 1-to-500 or 1-to-3000. It is not kept by many chemists. Browne has never seen nor heard of its causing any opacification of the cornea; and it does not, if cautiously used, injure instruments. It is extremely efficacious in all muco-purulent cases. Panas' solution of the biniodide of mercury is of great utility, and seems to possess more rapid penetrating power than the foregoing, and therefore is applicable to cases with corneal complications. It smarts a good deal, but gives rise to little permanent irritation, even if applied to ulcerated surfaces.

Antiseptic remedies that may be trusted to infiltrate the cornea, and pass into its substance or the interior of the eyeball, are much to be desired. Atropine, eserine, and their homologues are manifestly absorbed in a few minutes, but they have not even the feeblest antiseptic powers. The only two drugs to be at all depended on are quinine and pyoktanin. Both are absorbed slowly, but still they are absorbed, and have been observed modifying the appearance of the tissues.

Eyes that have been copiously treated with quinine have been known to present the peculiar bluish fluorescence characteristic of the drug in solution. Mr. Mackinley showed a case of a man—who if not born in the purple at least lived in it, at an aniline dye factory—whose cornea (and other tissues) were deeply tinted like stained glass. Neither drug can be rated high as antiseptics, but they are extremely useful in infiltrations and ulcerations of the cornea. So also may it be said of the time-honored remedy—the yellow oxide of mercury. This is one of our most valuable applications in chronic cases, but exceedingly treacherous. Its quality varies extraordinarily. Some samples irritate to a remarkable degree. Nothing in the external appearance has come under the writer's observation that might serve as a warning, but there are certainly subtle differences in the chemical constitution of the drug, as well as variations in the sensitiveness of the patients. With all its drawbacks, it has a wide range of utility. Remedies superior to the foregoing may be, probably will be, discovered. Even if that day arrives, we shall benefit but little if an empiric and

routine treatment remains the rule. The foundation of all rational treatment is twofold: (1) diagnosis; and (2) a knowledge of the pathology and natural course of the affection. It is no use trying to learn about drugs if we don't know the diseases. We may prescribe the very latest of the coal-tar derivatives of the *fin-de-siècle* advertising druggist, and be no better intellectually than the apothecary of the Middle Ages.

#### THE ADMINISTRATION OF CREOSOTE.

The *Journal des Praticiens* of December 12, 1896, recommends the following formula for the administration of creosote, the prescription being put up in cachets:

℞ Creosote,  
Benzoin, of each 15 grains;  
Powdered charcoal, 1½ drachms.

Triturate the creosote and the benzoin for a moment together and add by degrees the charcoal. This mass is then to be divided into five or ten cachets, each one of which will contain a proper dose. It is claimed that this prescription is very well borne by the stomach.

#### A PRESCRIPTION FOR INTERCOSTAL NEURALGIA.

According to the *Journal des Praticiens* of December 12, 1896, CHERON recommends the following prescription for intercostal neuralgia associated with uterine disturbances:

℞ Tincture of gelsemium, 100 drops;  
Simple syrup, 1½ ounces;  
Distilled water, 6 drachms.

Of this two to three teaspoonfuls may be taken twice or thrice a day.

[Such a prescription ought not to be used if the heart is at all feeble.—ED.]

#### AMYLIFORM.

Amyliform is a combination of formaldehyde and starch and is a white powder, without odor, insoluble in all liquids. It is, however, very stable and not easily altered. In the body it is decomposed slowly into formic aldehyde and starch. As is well known formic aldehyde is a useful bactericide, antifermentative and antiputrefactive, and it is stated that amyliform lends itself readily to the purposes of antiseptic surgery. Employed as a powder it diminishes in a rapid manner the secretions upon sores, particularly those which have a bad odor.

Langgard, who has used it both in major

and minor surgery, has never observed any symptoms of intoxication or local irritation from its use, such as sometimes follows the use of iodoform.—*Journal des Praticiens*, Dec. 12, 1896.

#### PLANTAR NEURALGIA.

JONES (*Liverpool Medico-Chirurgical Journal*, No. 32, 1897) calls attention to the silence of most text-books concerning this comparatively common and extremely obstinate complaint, and states that the discovery, description and treatment of the affection are almost entirely to be ascribed to American surgeons.

The disease may be defined as a painful affection of the plantar digital nerves, increased by pressure and usually located near the fourth phalangeal joint. The arches of the foot are usually described as two in number—the longitudinal and the transverse. The longitudinal may be considered to consist of two arches, an inner and an outer. The inner arch consists of the os calcis, scaphoid, three cuneiform bones, and the three inner metatarsal bones; the outer is made up of the os calcis, cuboid, and two outer metatarsals. The transverse arch is formed of the cuboid and cuneiform bones. The longitudinal arch has its concavity directed downward, and the transverse downward and inward. The two arches, longitudinal and transverse, taken together make up a semi-dome, and a part and parcel of the single structure. This semi-dome is opened internally, but closed behind externally and in front, and has its highest portion at the midtarsal articulation; thus the two feet placed together make a single dome.

These arches of the foot are essentially connected with the upright position. The weight of the body coming down the tibia enters the astragalus, the pressure points of which are directed downward and backward, and downward and forward. By the downward and backward lamellæ the weight of the body is continued to the ground through the os calcis and the heel, but the forward and downward carry it to the ground by the os calcis, cuboid, and metatarsal bones, all of which show definite pressure lamellæ. Taking the view that the arches are not separate, but merely integral portions of a whole, one is prepared to find that, along with a flattening of the longitudinal arch, the transverse arch is always affected, and *vice versa*. This statement can be proved to be correct by clinical observation. Associated with this

must be noticed the relative position of the heads of the metatarsal bones to one another. In a coronal antero-posterior section of a frozen foot, their position was: second in front of first by  $\frac{1}{4}$  inch; third behind second by  $\frac{1}{4}$  inch; fourth behind third by  $\frac{1}{4}$  inch; fifth behind fourth by  $\frac{3}{8}$  inch.

The head of fourth and that of fifth are considerably behind the preceding toe. Furthermore, one should note that the fourth branch of the internal plantar nerve communicates with the superficial division of the external plantar, and divides to supply the adjacent sides of the third and fourth toes. The position of this superficial division of the external plantar is of importance in the production of the pressure neuralgia of which this paper treats. In their course toward the toes the digital nerves, before they divide into the two nerves which will supply the contiguous sides of two adjacent toes, lie between, but not deeply between, the heads of the metatarsal bones. The fourth metatarso-phalangeal generally, but not invariably, is the affected joint; and Morton, in his original description of its pathology, advances a very plausible but only partially correct theory of its etiology. He says that the metatarso phalangeal joints of the first, second and third toes are found on almost a direct line with each other, while the head of the fourth metatarsal is from one-eighth to one fourth of an inch behind the head of the third, and the head of the fifth is from three-eighths to half an inch behind the head of the fourth: the joint of the third, therefore, is slightly in advance of the joint of the fourth, and the joint of the fifth is considerably behind the joint of the fourth.

The fifth metatarsal joint is so much posterior to the fourth that the base of first phalanx of the little toe is brought on a line with the head and neck of the fourth metatarsal, the head of the fifth metatarsal being opposed to the head of the fourth. On account of the character of the peculiar tarsal articulation, there is very slight lateral motion in the first three metatarsal bones. The fourth has greater mobility, the fifth still more than the fourth, and in this respect resembles the fifth metacarpal. Lateral pressure brings the head of the fifth metatarsal and the phalanx of the little toe into direct contact with the head and neck of the fourth metatarsal, and to some extent the extremity of the fifth metatarsal rolls above or under the fourth metatarsal. The mechanism of the affection, Morton asserts, becomes appar-

ent when the nerve-supply of the parts is considered. The branches of the external plantar nerve are fully distributed to the little toe and to the outer side of the fourth; there are also numerous branches of this nerve deeply lodged between these toes, and they are liable, Morton argues, not only to be unduly compressed, but pinched by a sudden twist of the anterior part of the foot. Any foot movement which may suddenly displace the toes when confined in a shoe may, he adds, induce an attack of this neuralgia.

Passing from the anatomy to a clinical description, three varieties may be described: (a) Plantar neuralgia of the first degree; (b) plantar neuralgia of the second degree; (c) plantar neuralgia of the third degree.

(a) In the first class one would comprise those cases where pain is occasionally felt along the metatarso-phalangeal joints during the performance of certain acts, but is immediately recovered from on desisting from such acts. In this stage there is no pain on pressing the spot. This stage is very common, and many readers will recall their own experiences in dancing or riding. It is a very usual complaint of the dancer that he has to rest because of aching behind his toes, and who of us has not met with the horseman anxious to rest his painful foot by riding without stirrups? In occupations where the body-weight falls on the anterior part of the foot, the affection is frequent, more especially where slippers or thin-soled boots are used.

(b) Those cases where characteristic symptoms quickly follow early attempts at walking after injury, due probably to a painful yielding of the transverse arch. The following case will represent a type of this variety: A young lady of twenty-four, of weak ligament type, whilst patting a horse after a ride, was trodden upon by it. The foot was considerably swollen, not very painful, and no lesion worse than pressure-bruising could be observed. She laid up for a week, and then walked about in house-boots or slippers. In less than three weeks she complained of considerable pain behind the fourth and fifth toes, and frequently had to rest. The pain subsided however almost immediately on abstaining from walking or standing. This pain lasted two months, and only left her when appropriate mechanical treatment was employed.

(c) The third or severe variety comprises those cases where symptoms appear idiopathically or remotely after injury, are persistent in character, do not yield to mechanical measures, and to all effect cripple the patient.

From an analysis of the foregoing cases one is enabled to formulate certain symptoms as constant, others as common, and some as exceptional. In all the cases a complaint was made of pain on walking. This pain was different in character from that of the so-called painful spasm of flatfoot, inasmuch as the pain in metatarsalgia is, in its intense area, strictly localized, while it is generally much more severe and paroxysmal. The painful flatfoot is oftenest found in the cold and bluish foot, while Morton's disease appears to be associated with healthy nutrition. In the milder varieties pressure has to be continued for a time before pain is manifest; in the severe cases less pressure produces much greater pain. In the first and second varieties the pain is neither so acute nor spasmodic as in the third. In all the reporter's cases there was pain on pressing either on the second, third, or fourth metatarso-phalangeals, and in the majority of cases opposite the fourth alone was the painful spot. This painful spot was in all cases best displayed by pinching the articulation between the finger and thumb. This could be effectively done without interfering with any of the other metatarsals, and is suggestive that Morton's explanation of the anatomy is not the whole truth. If the condition is usually accompanied by a broadened foot, due to a collapsing anterior arch during the act of walking, there would be separation rather than approximation of the metatarsal heads. Furthermore, if Morton's grinding theory is to explain all, why should a localized pinching applied to the metatarso-phalangeal alone give rise to pain. A radiograph may exhibit the broken line of metatarso-phalangeals, with the fourth as chief offender; but even making all allowances for the position of this articulation, it is not easy to conceive of a pure nipping of nerve as taking place where there is so much interspace. Taking into consideration also the fact that in thirteen cases grasping the front part of the foot in the hand gave relief, it is not in accordance with the theory of lateral pressure advanced by Morton, as such manipulation should increase, and not decrease, the paroxysm.

The explanation of the pain, having regard to the free mobility of the fourth and fifth, is much more probably a stretching or pressing upon rather than a nipping of nerve, and would accord more harmoniously with (a) yielding of the anterior arch; (b) relief experienced by circular compression; (c) pain

on local pressure. It is a theory which better accords with the exceptional instances of pain over the second and third joints. The mobility of the fourth and fifth allows of greater stretching when the transverse arch yields, and hence the frequency with which these joints initiate the trouble. Furthermore, most pressure in standing is placed upon the first and fourth metatarsal heads, while the frequency with which relief was obtained by frequently flexing the toes, which involves a lifting of the metatarsals, confirms one's belief that nerve pressure is the correct explanation of the lesion. In thirteen of the seventeen cases there was flattening of both arches. This suggests a weak ligamentous structure, and a stretching of the soft tissues of the waist of the foot. In thirteen out of seventeen cases circular compression below the instep gave relief. By this means, doubtless, the arch would be restored and the tissues of the sole relaxed. In the seven cases where a click in the joint gave a marked measure of relief, some subluxation—confirmed by lax ligaments—was suspected, but in only one case could the click be produced by manipulation.

That some neuritis is present in the severe varieties is suggested by the acute character of the pain, and by the statement volunteered by many that it felt like treading on something hot, and by the change sometimes noted in the nutrition of the toe. Particularly suggestive is the practice, during all stages of the affection, of rapidly flexing the toes; an act which cannot be performed without elevating the metatarsals, and relaxing the digital nerves from pressure and stretching.

Placing in order of frequency, symptoms which the author's cases have exhibited:

(a) Pain over metatarso-phalangeal region on standing or walking, only slightly relieved by mechanical contrivances.

(b) Pain on pinching the fourth metatarso-phalangeal.

(c) Relief of pain on circumferential pressure around base of toes, assisted still further by repeatedly flexing the toes.

(d) Sensation of walking on something hot.

(e) Presence generally of flattened arches of the foot.

In nearly all the cases reported prolonged treatment elsewhere had been adopted; and the complaint was generally ascribed to gout, rheumatism, or hysteria. We know how stretched or otherwise injured structures will

tempt a visit from any of the three diatheses; but apart from this possibility there was no evidence of its existence in the great majority of cases. In not one case was there any symptom of hysteria.

From an analysis of symptoms in seventeen cases it will be noted: That there was a history of injury in ten cases; that the third as well as the fourth joint was affected in three cases; that lateral pressure gave relief in fourteen; that reference was made to subluxation or reduction with click in seven; that there was flattening of both longitudinal and transverse arches in twelve; that ten patients were women, seven men; that three described sensation as if standing on something hot; that the ages ranged from twenty-four to fifty-eight, ten being between thirty and forty; that in one case symptoms were induced by pressure of callosities due to fracture; that in one case symptoms were induced by small fibroma of plantar fascia; that symptoms of gout, rheumatism, or hysteria were only found in two cases; that flexion of toes in the majority of cases was productive of relief.

The author's reasons for dissenting from the theory of causation as advanced by Morton may be summarized as follows:

1. The plantar digital nerves, instead of passing between the heads, lie on the transverse metatarsal ligaments, and when the foot is pressed upon, are pushed away from, not between, the bones.

2. It is not proved that the anatomical position of the heads of the third, fourth and fifth metatarsals is favorable to a nipping of the nerve on lateral pressure; on the contrary, there would be less escape were the metatarsal heads in absolute line.

3. That in the majority of cases a painful spot can be found and made intensely sensitive by pinching with the thumb on the dorsal and the forefinger on the plantar surfaces; that such spot is usually quite local, and would not respond to such pressure if, as asserted, the pinched and sensitive nerve were placed between the bones.

4. That in most cases a broadened foot, due to collapse of the anterior arch, accompanies the affection, rendering the digital nerves less liable to compression. This fact, in conjunction with another, viz., that a broad soled boot hardly gives any relief in the third degree of plantar neuralgia, is strongly at variance with Morton's theory.

5. That in a large number of cases grasping the foot around the metatarsal heads, thus approximating them, relieves the spasm.

6. That frequent flexing of the toes is an instinctive method of relieving spasm, the flexing of the toes being accompanied by slight approximation of metatarsal heads.

7. That manipulations of the foot by the surgeon, other than applying direct local pressure, rarely produce the pain.

Clinical observations accord much better with a theory of treading upon, rather than with that of pinching, a nerve; three anatomical facts strengthen this theory:

(a) The proximity to the painful area of the communicating fourth branch of the superficial division of the external plantar.

(b) The collapse of the anterior arch in most of the cases.

(c) The bulk of superincumbent body-weight in walking on the toes is borne on the first and fourth joints.

Tubby, in describing his cases, draws attention to the existence of corns over the painful areas. In not one of the writer's cases was this noticeable. When corns are found, however, they simply denote pressure-spots, and are situated over bony prominences. They point to pressure upon the nerve between the corn and articulation, and support the theory the author advances in contradistinction to the nipping of nerve between bone. His cases of plantar neuralgia due to fibroma of the plantar fascia and fracture of the metatarsal bone equally support his contention. Gibney, in an interesting article in the *Journal of Nervous and Mental Diseases*, states that if the bases of the metatarsal bones are tightly grasped, the distal ends are separated, and the nerves are no longer compressed. The writer's experiments do not bear out the conclusion Gibney has recorded; and even were it otherwise, the majority of patients obtain relief not by compressing the bases, but by compressing the heads, of the metatarsals.

If any normal foot be examined one will find that the two prominent spots upon which most of the body pressure is borne are opposite the first and fourth metatarsal joints. The fifth is also prominent, but is so mobile that it can be easily pushed to one side. This is a strong reason, therefore, why the fourth metatarsal should most frequently supply the painful area. The third and fourth become affected generally in cases of collapse of the anterior arch, where, instead of being concave on the plantar aspects, the metatarsals present a convexity, the second and third articulations forming the most prominent portion of the convexity.

From the persistence of pain in certain

cases, even after pressure has been withdrawn, and from the immediate sensitiveness when walking is practiced, one is inclined to believe that a neuritis of the plantar nerves involved exists in the more acute cases. This view is confirmed by the fact that even after a long rest, pinching the spot between the finger and thumb gives rise to severe pain.

The treatment of plantar neuralgia must vary with the stage of the affection. In the first stage the patient will do well to take the warning given, and by appropriate precautions prevent the development of the affection. This is done by attention to certain details:

(a) To abstain from continuing any action which produces the pain.

(b) To increase the depth of the inner aspect of heel, in order to produce slight inversion of foot.

(c) To wear thick soles, with well-fitting insteps, and roomy around the heads of the metatarsals.

(d) To insist that the sole be at least one-fourth of an inch thicker a little behind the bases of the metatarsals.

The preventive methods as applied in the first stage should also be directed to the cure of the second stage, with certain additions. These additions may be any or all of the following measures:

(a) A thick bar placed about half an inch behind the metatarsal heads.

(b) A band of non-irritating plaster around the instep.

(c) Massage of foot, with contrast baths of hot and cold water.

(d) Elevation of the foot of the bed at night.

The advantage of thick-soled boots is obvious; they prevent excessive mobility at the articulation, and minimize sharp bony pressure upon the nerves. The boots should be roomy at the toes, not merely to give more room to the metatarsal heads, but to allow freedom to flex the toes, and to perform other movements to avoid pain. The heel of the boot is slanted to correct the common tendency to valgus and to vary the pressure point. In cases where there is no collapse of the arch the heel may with advantage be elevated on the outer side to deviate body pressure.

Most important of all, however, is the thickening of the sole in the early cases (or bar in later) behind the metatarsal heads. This gives rest to the articulation, even during the act of walking, and is of more ad-

vantage than any other mechanical detail of treatment. This alteration, even in the case of inflamed or gouty toe-joint, allows the patient to travel in comparative comfort, and should always be prescribed in all the stages of plantar neuralgia—for a time even in those cases where an operation has been performed.

In the third stage of the affection nothing short of an operation is satisfactory. By this it is not meant that on no occasion can an advanced case be relieved by mechanical measures; on the contrary it can, and often is. But operative measures are so safe and simple, and other measures so prolonged and troublesome, that most patients do not hesitate which course to accept. Of operations, only three are radical and efficient: (a) Exsection of metatarsal head; (b) excision of joint; (c) amputation of metatarsal head and toe.

Short of these radical measures, we may employ any or all of the following methods: (1) Actual cautery; (2) heated needle into painful site, to destroy nerve; (3) hypodermic injections of carbolic acid; (4) part exsection of digital plantar nerve.

It will be noted that each of these surgical practices involves the plantar or walking aspect of the foot, a fact which seriously modifies its utility.

Of the radical operations, he strongly advocates the superiority of exsection over excision and amputation. It is simple, safe, and sure, and can be performed in the following way:

After the part has been carefully aseptitized an incision should be made a little over an inch in length, starting above the metatarso-phalangeal joint, and extending over the middle line of the toe. The extensor tendon is divided, the capsule opened, and the head of the metatarsal dissected out by a blunt instrument. With fine bone nippers the head is removed and the flexor tendon below divided. The wound is then stitched, and as a rule no vessels need securing. The after-treatment consists in keeping the patient in bed for about ten days, with the foot elevated. Massage should then be commenced, and the patient, with a bar under the foot, allowed to walk. There is usually nothing to hinder complete recovery in from five to six weeks, when boots such as earlier described should be prescribed.

#### DETECTION OF STONE IN THE BLADDER.

WILLIAM K. OTIS (*Journal of Cutaneous and Genito-Urinary Diseases*, February, 1897)

presents an instructive paper on the subject of stone in the bladder. The detection of stone in the urinary bladder is ordinarily a simple matter, presenting no extraordinary difficulties to the surgeon of average ability; but occasionally cases do occur in which the most skilful and experienced operators find themselves unable to establish a diagnosis in spite of every means at command. Stones, even of a large size, have escaped the most careful and minute examination by some of the most celebrated surgeons both of America and Europe. In actual practice the presence of stone is so frequently overlooked, especially when it complicates some other pathological condition of the bladder, that a thorough discussion of the various methods we have at our disposal for the detection of stone, and the relative utility of each, is timely.

The rational symptoms presented by patients with stone in the bladder are exceedingly variable in degree; they may all exist together, or one or more only may be present; or, even when the stone is of large size, there may be an entire absence of symptoms; or any or all of these symptoms may occur without the presence of stone. Otis calls attention to the fact that pain is usually the initial symptom, together with disturbances of micturition, and sooner or later cystitis almost invariably develops. Examination of the urine may demonstrate a larger amount of albumen present than would be accounted for by the amount of pus, although there may be no other indication of disease of the kidney, and this albumen will disappear after removal of the stone. Hemorrhage caused by the traumatic action of the stone on the bladder walls is a most frequent symptom, and according to Ultzmann always exists, though blood may not be present in sufficient amount to be visible to the naked eye. The bleeding usually occurs at the end of urination, and is more profuse after violent exercise. In cases of old patients with congestion of the prostate or hemophilia bleeding may become a very serious complication.

The author then refers to the value of the microscope as an aid to diagnosis in demonstrating the presence of crystals of lime oxalate, uric acid, or triple phosphate, indicating the nature of the stone, and the existence of pus and blood-cells, which may not be present in sufficient quantity to be recognized by the naked eye.

The history of the patient may give a clue as to the probability of the presence of stone.

Thus there may have been previous attacks of renal colic, in which one or more calculi were unaccounted for, pieces of catheter or bougies broken off in the bladder, the introduction of foreign bodies through the urethra, or through wounds of the bladder, or necrosis of neighboring bones, pieces of which may have ulcerated into the bladder and formed the nucleus for a stone.

Physical signs may exist without the presence of stone, and while they are exceedingly valuable, other methods are necessary to establish a positive diagnosis.

The most important method, giving definite information and easiest of application, is the use of the metallic sound or searcher. This instrument in general should be of small calibre, 15-20 F., have a short curve, in order that it may be readily rotated in the bladder, easily turned down behind a projecting prostate gland, and should be of sufficient weight to give it firmness in the hand. The presence of stone is definitely determined either by the sense of touch or an audible click given when the point of the instrument strikes the stone. Oxalates and urates give a loud, clear note, while phosphates and cystin stones only a feeble friction sound. There are many designs in the form of the searcher, differing from each other in more or less important particulars. The form most commonly used is one originated in 1860 by Sir Henry Thompson. This instrument consists of a silver catheter of 15 F., with a shaft ten inches long, having very thick walls to give the desirable weight, the eye being on the convex surface at its juncture with the staff. The curve is short, and the distal end slightly bulbous in form. The proximal end, or handle, consists of a roughened cylinder, one-half inch in diameter and two inches in length, to facilitate motion of the instrument. A scale with a slide is marked at this end of the instrument, to enable the operator to measure the size of stone. At the extreme end is placed a stop-cock to control the flow of fluid from the bladder. In 1891, despite the popularity of this instrument, Sir Henry became dissatisfied with it, especially with its ability to detect very small stones, the importance of which is so great to the patient, as they can then be removed with comparatively little risk; while if they are allowed to remain they are sure to increase in size, with a corresponding increase in the danger of removal. Sir Henry says: "There are two chief considerations to be borne in mind in designing such an instru-

ment: first, it should be so formed that all the necessary movements can be made with facility; that (a) the operator may pass it easily into the bladder and also know with certainty the direction of the beak when lost to view; and (b) that he should be able to rotate it with ease between the finger and thumb, when the beak is turned downward behind the neck of the bladder, especially when from enlargement of the prostate the well known depression exists there in which calculus is likely to lodge." The first condition is attained by using the flattened handle of a good old pattern; the second by placing close to it a small cylinder, a combination which now appears better than the entirely cylindrical handle which he originally introduced for lithotrites and sounds for the purpose named. The shaft of the sound should be rather slender, and the upper surface of the flat handle rough, while the lower is polished, so that the direction of the beak (upward or downward) is recognized by touch.

"Secondly, there should be special adaptation in the form of the beak to strike a very small concretion, and elicit a note therefrom. This is accomplished by flattening the beak a little in the opposite plane to that of the flat handle. It must be manifest to all on consideration that, long as we have been contented to employ a beak of cylindrical contour, this form is especially adapted to avoid direct impact on encountering a small calculus, since these bodies have mostly a nearly spheroidal or ovoid form, and naturally glance off when contact occurs." In fact, a blade flattened in the direction above described is more certain than a cylindrical one to make direct contact, and will transmit to the operator a greater sense of resistance and a more audible note. The wider measurement at the beak which he employs for ordinary purposes may be from 20-22 F., the narrower about 14-15, becoming a little thicker, though still flattened, toward the extremity. Such an instrument passes easily into any fairly healthy urethra, and in the presence of most forms of enlarged prostate, with rather increased facility in comparison with the ordinary form. It should never be forgotten in connection with seeking a small calculus that the dense fluid medium in which our instrument acts greatly increases the difficulty, as compared with the same action occurring in air, of obtaining rapid and direct contact with a small body of which the specific gravity is comparatively light; hence the need of flatness

and breadth of surface to ensure a direct blow, and the means of moving rapidly to ensure an audible note. It will be seen, however, that in this form of instrument the originator, in order to obtain solidity and distinctness of note, has abandoned one of the principal features which made his original searcher valuable—the ability to control the amount of fluid in the bladder, the instrument remaining *in situ*. In order to re-establish this advantage Otis has designed a searcher which exhibits all the points of Thompson's latest model, except that the shaft is hollow, the lumen being completely filled by a closely-fitting, polished rod connected with the flat portion of the handle, and held firmly in place by a bayonet catch. By this means all the firmness and weight of the solid instrument are retained, while if it becomes desirable at any time during the examination to vary the amount of fluid in the bladder, this may readily be done by removing the rod and allowing it to escape, or injecting a larger quantity.

Attempts to increase the volume of sound made by striking the stone are open to the objection that the added appliance makes the handling of the sound awkward. In certain cases the instrument may be made so sensitive that indications of stone are detected when none is present. The position of the patient is of importance. He should first be sounded while lying down, then standing, finally in the Trendelenburg position. Sometimes it is advisable to have him turn from one side to the other. The knee-elbow position may cause the stone to drop within reach. The bladder should usually contain about four ounces and should be examined both empty and distended. If the patient is hypersensitive the injection of choice is a  $\frac{1}{2}$ -per-cent. solution of cocaine, followed by instillation of four-per-cent. solution into the posterior deep urethra.

A favorite seat for calculus is the cavity of the bladder lying deeply behind the prostate, toward the cæcum. Ultzmann found that in eight out of ten cases in old men the calculi lodged in this region, and states that this pouch is due to the pressure of feces in the rectum which causes the entire bladder to be shifted towards the right and lifted and turned around its longitudinal axis.

The searcher enables us to determine the condition of the bladder walls, the mobility of the stone and its approximate size. The diameter is best determined by a small lithotrite. This instrument also enables us to

determine its chemical composition. An oxalate calculus will not yield. The shell of the urate stones is crushed, whilst the teeth sink readily into phosphatic or cystin calculi. On the teeth of the lithotrite will be found sufficient of the stone for chemical analysis.

When the presence of several stones is suspected the lithotrite should seize the one most easily grasped; it is then rotated and moved about in the bladder, when the operator can readily determine whether or not it comes in contact with other hard bodies.

The reasons for failure to detect stone in the bladder with searcher are: failure to introduce the instrument properly, the operator mistaking an enlarged prostatic sinus for the cavity of the bladder; low specific gravity of the stone, so that it flies away from the searcher without giving sufficient impact to be felt or heard; coating of the stone with mucous or blood-clots so that the characteristic sound and touch are absent, the condition being mistaken for a ruga of the bladder wall; encysted stone, where only a small portion may present in the bladder; and stones hidden in sacculations or pouches.

Mr. Buxton Browne has particularly pointed out a not uncommon and particularly annoying variety of the latter, which he terms the post-prostatic pouch, which consists in the horizontal portion of the trigonum of the bladder being pushed down between the enlarged projecting prostate in front, and a thickened and firm interureteral ridge behind. Where there is much intravesical prostatic projection the pouch may literally be roofed over by this prostatic outgrowth. Calculi in this pouch cause much pain, as the trigonum of the bladder has a larger nerve supply than any other portion. Lying as this pouch does in front of and below the orifices of the ureters, it is a perfectly-contrived trap for catching and retaining renal calculi upon their entrance into the bladder, and it is readily seen how favorably they are placed there for growth. If such a condition is suspected the beak of the instrument should not merely be reversed, but a thorough examination should be made of this extremity for the slit-like opening between the intravesical prostatic growth and the interureteral ridge, which may be the sole means of access to the large prostatic pouch. Browne has designed a sound with a beak like a flat-bladed lithotrite to make this investigation. It slips with great facility behind the projecting lobe of the prostate, allowing the place to be as fully

explored as is possible with any instrument passed into the natural channel.

Digital pressure through the rectum sometimes affords help in this exploration. Bimanual palpation is an extremely valuable means of detecting large calculi, and for finding small fragments the lithotrite tube and an aspirator are useful. The cystoscope is serviceable in cases in which its introduction is possible. In certain cases the diagnosis can only be cleared up by cystotomy. Should this be indicated the suprapubic operation is the one of choice.

#### *SURGERY OF THE LUNG.*

In the year 1710, nearly two centuries ago, Baglivus suggested that cavities in the lung might be successfully treated by operation. During the next century and a half an occasional operation was performed for the relief of pulmonary affections, but the surgery of the lung was unsystematic and largely experimental until Graux in 1850 reported the results of thirteen operations. All these cases were unsuccessful, however, and these results combined with other similar failures retarded the progress of pulmonary surgery for another quarter of a century.

A fresh impulse was given to this branch of surgery some fifteen or twenty years ago, when numerous successful experiments on animals, where portions of the lung, and even entire lobes, were excised, led to the hope that the same success might follow operations on the human lung. This expectation, however, has not been fully realized. Especially is this true in regard to tubercular process, which would offer a vast field for operative interference were success to follow such treatment. In this class of cases there seems to be but little hope of benefit to be derived from excision of tubercular foci. Reclus, in a most admirable address which he delivered before the French Surgical Congress in 1895, said: "Resection of the lung for tubercular disease seems to me condemned past all appeal." This judgment may be somewhat too severe, and yet it probably expresses the view of most conservative surgeons on this subject.

The results of simple incision into tubercular cavities have been somewhat more favorable. A number of patients have been benefited by this procedure, and in certain cases this operation seems indicated. A successful termination must be exceptional, however, as the original focus of disease must

still remain, and probably other foci also. Reclus reports eight such operations upon an equal number of patients, only two of whom died, while five were improved or cured. He states, however, that all were carefully selected cases. Laufert and Worth have calculated that out of 100 such cases, five die at once as the result of operation, ten die within a fortnight, fifteen more inside of a month, ten are improved, and zero represents the number of recoveries. Paget reports twenty-four operations, with nine deaths, five recoveries, and five improvements.

Operation for pyopneumothorax, as the result of tubercular ulceration, has been performed in a number of patients, in two of whom the opening was successfully closed by suture. The difficulty of locating the perforation must be great, however, and at best temporary relief only can be afforded.

The results of operation for growths in the lung are equally disappointing. When carcinoma or sarcoma occurs primarily the growth is in all probability so extensive before the diagnosis can be made that extirpation is impossible. In some cases where the malignant tumor has extended to the pleura and lung from the chest, it is possible that extirpation might be successfully accomplished.

In abscess, gangrene, and hydatid cysts, sufficient experience has accumulated to enable us to judge approximately of the risks of operation and of the chances of recovery. The results are becoming more and more favorable, and undoubtedly will be still more encouraging as soon as physicians can be convinced that operation is not attended with great risk, and that it offers a fair chance for recovery.

The results of operation for pulmonary abscess are certainly full of promise. Thus Fabricant reports thirty-eight cases, with twenty-nine recoveries and nine deaths. Reclus reports, out of twenty-three operations which have been performed within the past ten years, twenty cures and three deaths. The old idea that adhesions between the lung and parietal pleura were a requisite for successful operation is passing into oblivion. Adhesions are unquestionably of great advantage. When they exist the danger of infecting the pleural cavity and thus exciting pyopneumothorax is very slight, and the incision into the abscess cavity is a comparatively simple operation. Many successful operations have been performed, however,

where there are no such adhesions, as for example the cases recently reported by Smith and Frederick Treves in the *Lancet*, and by Northrup in the *New York Medical Journal*. If adhesions are absent the operations can be carried out in two stages: at the first, suturing the two pleural layers; at the second, opening the abscess after a delay of a few days. Unfortunately, however, such delay is generally inadmissible—it means death. The abscess must be opened at once. In certain cases the parietal pleura may be sutured to the lung, but generally the patient's condition is such that the operation must be rapidly completed, the pleural cavity being protected as well as possible by sponges and gauze.

In gangrene the mortality without operation is about eighty per cent. In certain cases of diffuse gangrene, operation is out of the question, and the case is hopeless. In circumscribed gangrene operation offers to the patient a fair chance of recovery. Excepting a few cases of gangrene occurring in young subjects, where the patch is small and near the apex, it is a question whether operation should not be advised as soon as the diagnosis is made in every case of circumscribed gangrene where the general state of the patient or some intercurrent disease does not render all treatment hopeless. As in abscess, so in gangrene; the operation, if otherwise indicated, should be performed, adhesions or no adhesions.

Another reason for delay which is sometimes advocated is that operation is not indicated until after the stage of consolidation has passed and deliquescence begun. The latter stage, however, is generally reached before the diagnosis has been made. Of course the patient may recover without operation, but the danger of sepsis, or the conversion of a circumscribed into a diffuse gangrene, more than counterbalances the risk of an operation. These risks are not very great, as may be judged from the statistics of Heydweiller, who collected forty cases treated by operation prior to 1892, with twenty-two recoveries, four improvements, and fourteen deaths. The more recent cases of Reclus number fourteen operations, eleven of the patients being cured, one being improved, and only two having died.

In cases of bronchiectasis the results of operation seem to be less hopeful. More than one cavity generally is present. One may be incised and healed, but others are left. Reclus reports twelve operations, eight of

which terminated fatally, four of the patients being improved, but none cured. Paget reports five cases, all of whom were improved, but he adds that all were exceptional cases. The conclusion of Truc seems correct: "When the cavity in the lung is the essential lesion, when the symptoms of septic absorption dominate the scene, when there is high fever and the patient is shaken by cough and exhausted by profuse expectoration, then without raising vain hopes and simply to alleviate suffering we may have recourse to incision of the lung. Now and again a marked improvement has been noted."

The results of operation for hydatid cysts have been most satisfactory, indeed more so than for any other pulmonary affection. Paget has collected forty-five cases thus treated, thirty-seven of the patients being cured, and six having died. In this condition operative interference is always indicated. — *Medical News*, Feb. 13, 1897.

#### TOTAL HYSTERECTOMY AT TERM: CONTRACTED PELVIS.

PINARD and SEGOND treated a pregnant woman who was much deformed. There was scolio-kyphosis and asymmetrical pelvis; the anterior and posterior bony boundaries on the right side almost touched. It was agreed to let pregnancy go on to term and then to remove the uterus. On December 16, 1896, the operation was performed directly pains set in, term having been reached. A very free abdominal incision was made; then the uterus was pulled out, and immediately afterwards the upper part of the wound was closed by forceps applied to its edges so as to prevent prolapse of intestine. The elastic ligature was applied and the child extracted; it weighed ten pounds, and was living and strong. Then the placenta was extracted. Pressure forceps were applied to the edges of the wound in the uterus, and that organ was then amputated, with its appendages, by a continuous incision from left to right. On January 19 the patient was quite well. — *British Medical Journal*, Feb. 19, 1897.

---

#### PRIMARY SARCOMA OF THE SMALL INTESTINE.

MERMET records the case of a woman aged thirty-two, who came under observation with attacks of painful diarrhea, and a tumor below and to the left of the umbilicus, which

was thought to be a pyosalpinx adherent to the intestine. Laparotomy was performed, and the tumor was then found to involve the jejunum at one meter's distance from the duodenum. The portion of intestine was resected, but the patient died the next day. The growth was twenty cubic centimeters in length, and had sharp margins. The affected part of the gut was enlarged to the size of the transverse colon, its lumen also being increased in size. The mesenteric glands were enlarged. At the operation no other secondary growths were seen, but there was no necropsy. The growth was a small round-celled sarcoma, starting on the submucosa, and had infiltrated all the coats of the bowel. The author lays stress on the points of distinction between sarcoma and lymphadenoma of the intestine. Reference is made to twenty-three other cases of sarcoma of the small intestine. It occurs much oftener in males than in females; usually between thirty and forty years of age, while lymphadenoma occurs earlier. In eight out of fourteen cases recorded by Balzer the growth was a small round-celled sarcoma.—*British Medical Journal*, Feb. 6, 1897.

REPORT OF SIXTY-NINE CASES OF AM-  
PUTATION AT THE HIP-JOINT BY  
THE WYETH METHOD.

JOHN A. WYETH (*Annals of Surgery*, vol. xxv, No. 2) records a death-rate of 13.9 per cent. in sixty-nine cases. The factors in the fatal cases were hemorrhage before operation, or shock. Of forty cases of sarcoma four died; of twenty-two cases of inflammatory bone disease three died. The efficiency of the method in controlling hemorrhage was demonstrated to be absolutely satisfactory in every instance but two. In one case the constriction was not tight enough; in another case the pins were not sufficiently strong.

Wyeth's method is as follows: The patient should be placed with the sacrum resting upon the corner of the operating table, the sound limb and arms being wrapped with cotton batting and thoroughly protected from unnecessary loss of heat. The limb to be amputated should be emptied of blood by elevation of the foot, and by the application of the Esmarch bandage, commencing at the toes. Under certain conditions the bandage can be only partially applied. When a tumor exists, or when septic infiltration is present, pressure should be exercised only to within five inches of the diseased portion for

fear of driving the septic material into the vessels. After injuries with great destruction, crushing, or pulpefaction, one must generally trust to elevation, as the Esmarch bandage cannot always be applied. While the member is elevated and before the Esmarch bandage is removed the rubber-tubing constrictor is applied. The object of this constriction is the occlusion of every vessel above the level of the hip-joint, permitting the disarticulation to be completed and the vessels secured without hemorrhage and before the tourniquet is removed. To prevent any possibility of the tourniquet slipping employ two large steel needles or skewers, three-sixteenths of an inch in diameter and ten inches long, one of which is introduced one-fourth of an inch below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse superficially for about three inches the muscles and fascia on the outer side of the hip, emerging on a level with the point of entrance. The point of the second needle is thrust through the skin and tendon of origin of the adductor longus muscle half an inch below the crotch, the point emerging an inch below the tuber ischii. The points should be shielded at once with cork to prevent injury to the hands of the operator. No vessels are endangered by these skewers. A mat or compress of sterile gauze, about two inches thick and four inches square, is laid over the femoral artery and vein as they cross the brim of the pelvis; over this a piece of strong white rubber tubing, half an inch in diameter when unstretched, and long enough when in position to go five or six times around the thigh, is now wound very tightly around and above the fixation needles and tied. If the Esmarch bandage has been employed, it is now removed. Excepting the small quantity of blood between the limit of the Esmarch bandage and the constricting tube the extremity is bloodless, and will remain so.

In the formation of the flaps the surgeon must be guided by the condition of the parts within the field of operation. When permissible, the following method seems ideal: About six inches below the tourniquet a circular incision is made down to the muscles, and this is joined by a longitudinal incision commencing at the tourniquet and passing over the trochanter major. A cuff that includes everything down to the muscle is dissected off to near the level of the trochanter minor. At about this level the remaining

soft parts, together with the vessels, are divided squarely down to the bone by a circular cut. At this stage of the operation the central ends of the divided superficial and deep femoral veins, as well as the arteries, are in plain view and should be tied with good-sized catgut. This done, the disarticulation is rapidly completed by lifting the muscular insertions from the trochanters and digital fossa, keeping very close to the bone with knife or scissors, and holding the soft parts away with retractors. The capsular ligament is now exposed and divided, and by forcible elevation, adduction and rotation of the femur, it is widely opened, the ligamentum teres ruptured, and the caput femoris dislocated. If properly conducted up to this point, not a drop of blood has escaped, excepting that which was in the limb below the constrictor when this was applied. The remaining vessels which require the ligature should now be sought for and secured. These are: the saphena vein, which on account of its proximity to the main trunk should be tied; the sciatic artery, which will be found near the stump of the sciatic nerve; the obturator, which is situated between the stump of the adductor brevis and magnus, usually about half-way from the centre of the shaft of the femur to the inner side of the thigh, the vessel being on a level with the anterior surface of the femur; the descending branches of the external circumflex, two or three in number, usually found about an inch and a half outward and downward from the main femoral vessels beneath the rectus and in the substance of the crureus and vastus externus. The descending branches of the internal circumflex are insignificant, and are usually found on the level of the femoral vessels in the substance of the adductor longus and between it and the adductor brevis and pectineus.

In tying the larger femoral vessels Wyeth makes it a rule to dissect both the superficial and deep femoral stumps back from one-half to three-fourths of an inch, so that he can apply the ligature behind any of their branches which may have been divided close to their points of origin, and does not hesitate to include the large veins in the same ligature in order to save time. With the vessels mentioned quickly secured, there is really no necessity for even temporarily loosening the tourniquet. If the operator is not sure that he has found and securely placed the ligatures upon these larger vessels, it is a simple matter to slowly loosen the grasp of the

tourniquet until the pulsation of the larger trunks is perceptible. No attention should be paid to the general oozing from the large muscular surfaces which have been divided. If every oozing point were ligatured, from half an hour to an hour would be consumed in securing a dry wound in the majority of cases. In order to hasten the operation and stop the oozing, introduce a snug packing of sterile iodoform-gauze ribbon into the cavity of the acetabulum and the space between the muscles from which the bone has been removed, leaving one end of the ribbon to pass between the flaps for the purpose of its removal. With a long, half-curved Hagedorn-Fowler needle armed with good-sized catgut, deep sutures are passed through the stumps of the divided muscles in such a way that large masses of muscles are brought tightly together when these sutures are tied, taking two to four inches in the grasp of each suture. The needle is not passed in the proximity of the large vessels or the sciatic nerve, but in all other directions the muscles are rapidly quilted together. This effectively and rapidly controls all oozing. Nothing remains but to close the flap with silkworm-gut sutures, and cleanse it off thoroughly dry, seal it with collodion in its entire extent to prevent any infection from the genital or anal region, apply a large, loose dressing of iodoform and then sterile gauze, and a light bandage over the first light dressing. The pins are then removed and the remainder of the dressing completed. Preliminary pressure of the light dressing prevents oozing, and the wound remains dry.

---

#### MIDWIFERY AND DISEASES OF WOMEN.

E. SAVA records the case of a multiparous woman pregnant at the eighth month, who was brought into hospital suffering from a round penetrating wound with irregular ecchymosed edges in the epigastric region. She had fallen on a sharp piece of wood which had caused the wound. The patient was conscious, her pulse was small and frequent, and the temperature subnormal. There were no signs that labor had set in, and the uterus was unwounded; but as there was evidently internal hemorrhage, laparotomy was performed. The source of the bleeding was found in a laceration of the epiploon; this was sutured, and the hemorrhage ceased. Some saline solution was left in the peritoneal cavity, as is done in cases of grave anemia, and the abdomen was closed in the usual

way. The woman left the hospital twenty days later, and soon afterwards she was delivered of a living, well-developed child. She was seen by the author a month after the confinement, and she remained well. The case is interesting because the pregnancy, notwithstanding the triple traumatism (the fall, the puncture of the abdomen, and the laparotomy), went on uninterruptedly to the full term.—*British Medical Journal*.

#### THE TREATMENT OF CHRONIC BRONCHITIS.

In the *Revue de Thérapeutique Médico-Chirurgicale* of January 15, 1897, Dr. LYON contributes an article upon this frequent and often troublesome affection. He first points out that chronic bronchitis is nearly always a secondary condition following acute bronchitis or dependent upon organic disease such as emphysema, Bright's disease, or various cardiac affections. Acute bronchitis he thinks is very apt to become chronic in those persons who have a neuroarthritic tendency—or in other words those who possess a tendency to gout and allied affections. Sometimes, too, chronic bronchitis exists simultaneously with chronic disease of the nose and pharynx, and the relief of these lesions cures the bronchitis. Quoting Laennec as to the various forms of chronic bronchitis he divides them into the dry and moist form, the latter form in turn being divided into what is known as the mucous and purulent. Sometimes this purulent secretion becomes putrid, when it is known as "putrid bronchitis;" and finally there is, rarely, a membranous condition known as pseudo-membranous bronchitis. In association with these complications chronic tracheitis is sometimes present.

The treatment of bronchitis divides itself into several forms: first, the modification of the function of the bronchial mucous membrane so as to alter the secretion and also with the object of combating congestion; second, we must facilitate expectoration; third, we must calm the cough; fourth, we should improve the general health of the patient by hygienic and other measures. The agents which modify the bronchial secretion are numerous. The chief ones are those which after absorption are eliminated by the respiratory passages, and consist in greater part of the balsams, gum resins of plants containing essential oils, sulphur and its compounds, and the iodides. Of the first class of substances we may cite in particular tar, bal-

sam of tolu, benzoin, turpentine and terpine, eucalyptol and creosote. The inconvenience associated with all these remedies is that they exercise an irritant influence upon the stomach. Copaiba, which is rarely employed because it has not a good reputation, nevertheless is very efficacious. Its essence is eliminated by the respiratory mucous membrane, and the resin is slowly eliminated by the kidney. Dujardin-Beaumetz recommended its association with tar. He prescribed four to eight capsules containing seven grains of equal parts of copaiba and tar.

Turpentine is usually employed in capsules holding three to four minims, six to eight of which are taken daily, but terpine has quite largely taken its place. The great difficulty with the administration of creosote in cases of bronchitis is the irritant influence which it exercises upon the stomach. There is no doubt, however, that creosote aids in getting rid of the secretion and acts deleteriously upon the tubercle bacillus. The balsams which have been mentioned are usually employed by inhalation, being added to hot water, and the steam arising therefrom inhaled.

The following prescriptions may be employed internally in using the medicines already suggested:

℞ Tar, 75 grains;  
Balsam of tolu, 75 grains;  
Benzoate of sodium, 1 drachm.

Make into 40 pills and give four a day.

℞ Terpinol, 2 grains;  
Benzoate of sodium, 2 grains;  
Sugar, sufficient quantity.

Make into one pill and give six to twelve a day.

℞ Terpine, 75 grains;  
Glycerin and alcohol, 2½ ounces;  
Simple syrup, 2½ ounces.

A dessertspoonful three or four times a day.

℞ Turpentine, 30 minims;  
Tar, 30 minims;  
Balsam of tolu, 1½ drachms;  
Benzoate of sodium, a sufficient quantity.

Make into 80 pills and give six or eight a day.

℞ Terpine, 75 grains;  
Brandy, 2½ ounces;  
Syrup of lettuce,  
Syrup of tolu, of each 3¼ ounces.

One to two dessertspoonfuls twice or thrice a day.

Eucalyptol may be prescribed in capsules containing one grain; these may be given three or four times a day.

Lyon thinks that eucalyptol is preferable to turpentine, as it is not so apt to produce disturbances of the stomach and kidneys.

Benzoin may be given in the dose of half a drachm of the tincture several times a day with very good results; or the following may be used:

- ℞ Tincture of benzoin, 15 to 30 minims;  
Tincture of canella, 2½ drachms;  
Wine, 4 ounces.

In other cases it is wise to prescribe the following:

- ℞ Terpene and pure benzoic acid, of each 2 grains;  
Codeine, ¼ grain.

Make into a pill and give four to six of these a day.

Or creosote may be given in pill form as follows:

- ℞ Creosote, 2 drachms;  
Almond soap, a sufficient quantity.

Make into 80 pills and give eight or ten a day.

The pilular form of administration of this drug is very satisfactory, in direct contrast with the use of creosoted wines which have been employed in the treatment of pulmonary tuberculosis, with the result of very frequently provoking digestive disturbances. Because of the useful influence exercised by sulphur over the mucous membranes the various natural sulphur waters and also those which are made artificially may be employed. None of the natural waters are as good after transportation as they are at the spring. As sulphur tends to congest the bronchial mucous membrane it is only to be employed during the period of the decline of the bronchitis when the secretion resists the action of the balsams. The iodides are particularly efficacious in those cases in which the bronchitis is associated with emphysema, particularly if arterio-sclerosis is present. They liquefy secretions and aid in their expectoration from the lung. They have, however, the inconvenience attendant upon the administration of any iodide, namely, the loss of appetite and the other evidences of iodide intolerance. They must therefore be given with prudence. It is well to interrupt their administration every three or four days for a short period. The doses should vary from three to fifteen grains a day. It is advantageously associated with codeine or with belladonna. The following prescription may be used:

- ℞ Distilled water, 12 ounces;  
Iodide of potassium, 3 to 8 drachms;  
Fluid extract hyoscyamus,  
Fluid extract belladonna, of each 1 fluidounce.

Dessertspoonful of this is to be taken at night before retiring, and again if dyspnea in nocturnal paroxysms appear.

[As these extracts are not entirely soluble in a watery menstruum this mixture will have to be shaken before it is used.—ED.]

Should the element of pulmonary congestion be marked, ipecac and ergotin in minute doses are often useful, and the ipecac may be combined with terpene and ergotin. As a rule, however, the ergotin is best administered in suppositories as follows:

- ℞ Ergotin, 5 grains;  
Powdered opium, 1 to 2 grains;  
Extract of hyoscyamus, 1-6 grain;  
Cacao butter, a sufficient quantity.

This is to be made into a suppository and introduced each night into the rectum. If we desire to use ipecac the following may be given:

- ℞ Syrup of ipecac, ¼ ounce;  
Syrup of acacia,  
Syrup of tolu, of each 4 ounces.

Two to four teaspoonfuls a day may be given in hot water.

So far as expectorant medication is concerned, we find that if the lung is exceedingly full of mucus it may be necessary to produce emesis by prescribing ipecac. Or if the patient is a strong, vigorous man we may prescribe tartar emetic in minute doses. In other cases the following prescription is useful:

- ℞ Chloride of ammonium, 45 grains;  
Extract of hyoscyamus, 15 grains;  
Powdered ipecac and powdered alum, of each 7 grains.

Make into fifty pills and give four a day.

Or the following powders may be given:

- ℞ Dover's powder,  
Powdered squill, of each 10 to 20 grains;  
Powdered eucalyptus, 1 drachm.

Make into thirty cachets and give three a day.

For the arrest of cough the same remedies are useful as may be employed in acute bronchitis, such as opium, belladonna, aconite, and cherry-laurel water. Where the secretion is thick the bromides are often very useful.

Hygienic treatment consists in the use of frictions and hydrotherapy, in sending the patient to a health resort, in the use of iodide of iron, cod-liver oil, bitters, and cinchona, and in the employment of arsenic and of cardiac stimulants such as digitalis and caffeine. Where there is a bronchorrhea full doses of ergot or hyoscyamus and of arsenic are of value, and for tracheitis inhalations of menthol vapor derived from a menthol in-

haler, or made by putting a few crystals of menthol in a hot spoon, are exceedingly useful.

For putrid bronchitis with fetid expectoration we should administer essence of turpentine, eucalyptus, carbolic acid, and creosote. Inhalations of oxygen are also valuable in such cases, and it is said that subcutaneous injections of eucalyptol made as follows are valuable:

℞ Eucalyptol, 5 drachms;  
Liquid vaselin, 2 grains.  
Inject one to two teaspoonfuls.

Lyon also quotes Da Costa as having recommended oil of sandalwood in doses of five drops four times a day.

In pseudo-membranous bronchitis we should treat the disease as we would diphtheria, by diphtheria antitoxin or antistreptococcic serum. Iodide of potassium may also be useful. In the chronic bronchitis of children, after being sure that no rickets, adenoid vegetations or hypertrophic rhinitis are the cause of the trouble, we should administer cod-liver oil, arsenic, and bitter tonics.

---

## Reviews.

---

**A PRACTICAL TREATISE UPON DISEASES OF THE SKIN.** For Students and Practitioners. Fourth Revised Edition. By James Nevins Hyde, A.M., M.D., and Frank H. Montgomery, M.D.  
Philadelphia: Lea Brothers & Company, 1897.

Any book dealing with general medicine, and therefore of interest to the all around practitioner, which runs through an edition in the period of three years may well be considered successful, and when we consider that this volume has reached its fourth edition in that period of time, although it deals solely with skin diseases, it will be understood at once that it must possess sterling merits which will recommend it not only to the dermatological specialist, but to the general practitioner as well. From the standpoint of the latter, we have looked over its pages for the purpose of discovering what the points were which have proved so attractive to many practitioners. One of these is the large number of illustrations which render the diagnostic points which are mentioned in the text clear to those who have not had the advantage of practical courses in dermatology; and second, there are many instances in which the recommendations as to treatment are fortified by the practical illustration of their method of application.

**ARCHIVES OF CLINICAL SKIAGRAPHY.** Edited by Sidney Roland, B.A.

London: The Rebman Publishing Company, 1896.  
Philadelphia: W. B. Saunders, 1897.

This, the last number of Volume I of the "Archives of Skiagraphy," contains a series of plates illustrating the anatomy of a double monster, the condition of the feet in a patient who had six toes, a fracture of the olecranon treated by suturing with wire, and similar subjects.

Such a journal must possess considerable interest to two classes of scientific investigators: first, those who are interested in the Roentgen rays from an electrical point of view; and second, those who are wont to employ these rays in the differentiation and diagnosis of disease.

**INEBRIETY: ITS SOURCE, PREVENTION, AND CURE.** By Charles Follen Palmer.

Fleming H. Revell Company, New York, Chicago, and Toronto, 1897.

This is a small essay of just one hundred pages, closing with a curious diagram which seeks to illustrate the author's views in regard to the important subject which he discusses.

The first chapter is upon "Nervous Mental Organization," the second upon "The Inebriate's First Step Toward a Cure," and after two intervening chapters there is a final one upon "The Moral Characteristics and Various Types of the Inebriate."

**ORGAN DISEASES IN WOMEN.** Notably Enlargements and Displacements of the Uterus and Sterility Considered as Curable by Medicines. By J. C. Burnett.  
Philadelphia: Boercke & Tafel, 1897.

This is a little book of the style of a child's primer, devoted to the consideration of conditions of sufficient gravity to require a scientific treatise to consider them. As long as individuals are willing to resort to futile methods of treatment such as are recommended by Dr. Burnett, just so long will practitioners of the class he represents continue to exist. It is simply a case of supply equaling the demand.

We regret that this book should have been published. It is written by one professing to practice Homeopathy, who in no way represents the advanced and enlightened stand which some of those who profess to practice Homeopathy are now taking in regard to the methods which should be employed in the practical treatment of diseases, medicinal or operative. An ignorant midwife could have produced a more valuable contribution to medical literature.

**THE MEDICAL ANNUAL AND PRACTITIONER'S INDEX.**  
A Work of Reference for Medical Practitioners. Fifteenth year.

Bristol, England: John Wright & Company. New York: E. B. Treat. 1897.

The Medical Annual for 1897 contains 629 octavo pages which deal not only with therapeutic advances but also with the general topics of surgery, medicine, the various specialties in medical practice, and a description of new and valuable apparatus. It is, like previous editions of this well known reference book, copiously illustrated by pictures which as a rule are quite up to if not beyond the quality usually found in the best medical text-books of the day. In the present volume colored Plate XIX showing various pathological conditions of the larynx and vocal chords, and Plate XXIII showing psoriasis, seem to us worthy of note. It is hardly necessary to add that the publishers have called to their aid the use of the skiagraph for the elucidation of the text where it was necessary. The English edition closes with a large number of pages devoted to the exhibition of new surgical and other apparatus, the names of various publishers, and a large number of advertisements of articles which will prove useful to the general practitioner. It is evident that a constant effort is being made by the publishers to maintain the reputation already acquired by this useful publication.

**THE YEAR-BOOK OF TREATMENT FOR 1897.** Prepared by many Collaborators.

Philadelphia: Lea Brothers & Company, 1897.

To those who are accustomed to looking forward to the yearly publication of this useful summary of therapeutic literature, we are confident that the present issue will give much satisfaction. It is now, as it has always been, a well prepared digest of therapeutic literature for the year, made by men exceedingly well fitted by experience for the responsible positions of abstractors. Each author knows full well exactly what is valuable and what must be cast aside as being useless to the general practitioner.

The paper, printing and binding are beyond reproach, and the cost of the volume is so moderate as to place it within reach of every physician.

**DISEASES OF THE STOMACH.** By Dr. C. A. Ewald. Translated and edited, with numerous additions, from the Third German Edition by Morris Manges, A.M., M.D. Second Revised Edition.

New York: D. Appleton & Company, 1897.

This classical book upon Diseases of the Stomach has not only proved itself very popu-

lar in Germany, but was translated in this country some years ago by Dr. Manges, and in England has been published in the list of the New Sydenham Society. The first American edition appeared in 1892 and speedily made for itself a place in American medical literature, first, because no similar book was to be had in the English language; and second, by reason of the fact that it was of itself a most valuable contribution to medical literature. Although the present edition is taken from the third German edition, which appeared in 1893, Dr. Manges has by careful editorial work included in the text, or in footnotes, everything in English and American literature which is of any value concerning the study of gastric disorders, so that the book is to-day not only a mirror of German study and practice, but also reflects the views of the best specialists upon this subject in this country.

We do not know of any other volume dealing with this or any other branch of medicine in which the references seem to be so well chosen and so judiciously quoted.

So much work has been done during the last four or five years in the study of gastric disorders in this country that we are practically the equals of our German brethren in the study of these lesions, and, perhaps because Americans are supposed to suffer from gastric disorders, have far surpassed our English cousins in this line of work.

Those who have the earlier edition of this book will, we are sure, hasten to purchase the new one, and those who have not the earlier edition certainly ought to enlighten themselves by having this one in their libraries.

**CHIRURGIE DES VOIES URINAIRES.** Etudes Cliniques par le Dr. E. Louveau. 2me Volume.  
Bordeaux: Feret & Fils, 1897.

This work, like the one issued three years ago by the same author, is simply a close clinical study of disease as it occurred in the author's hospital and private practice. It appears in the form of case reports with practical comments. Many of these cases have already been published in current journals, but since they are properly classed under one branch of surgery the author believes it serviceable to collect them in a single volume. There is one case of paroxysmal hemoglobinuria studied with unusual care.

The first paper in the book is devoted to painful micturition of uterine origin, with reports of cases. Among interesting articles found in this volume may be mentioned a

well-illustrated paper upon Glandular Hypospadia; the description of an efficient hypogastric urinal; a discussion of the relation of urethral spasm to lithotrity; A Case of Vesical Papilloma; reports of Urethral Tumors; and Cancer of the Kidney.

This work should be valuable to those who are especially interested in genito-urinary surgery.

**LECTURES ON APPENDICITIS AND NOTES ON OTHER SUBJECTS.** By Robert T. Morris, A.M., M.D. Second Edition, revised and enlarged. With illustrations by Henry MacDonald, M.D.  
New York: G. P. Putnam's Sons, 1897.

This collection of lectures, the author states, includes the substance of his teaching to the students at the Post-Graduate Medical School of New York, and also a series of notes on other subjects which have particularly interested his class.

The first chapter is devoted to preparation of the surgeon and patient and covers the general rules of surgical antisepsis. The second chapter is devoted to the anatomy of the appendix. Then follows a discussion on appendicitis, with surgical treatment and a table of cases.

The author's views on this subject are expressed in an unusually clear, original, and forceful manner. Following this portion of the book on appendicitis, there are a number of useful papers, exhibiting the author's ingenuity and success in dealing with unusual surgical conditions, and his keen observation of pathological processes.

The book is admirably printed and beautifully illustrated, and is worthy of the reputation of its distinguished author.

**A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS.** In Photo-lithochromes from Models in the Museum of the Saint Louis Hospital, Paris. With Explanatory Woodcuts and Text. Edited by J. J. Pringle, M.B., F.R.C.P.

London: The Rebman Publishing Co., Ltd. Philadelphia: W. B. Saunders. 1897.

The photo-lithochromes of this admirable work, published by Saunders (Part VIII), and elucidated by Besnier, Fournier, Tenneson, Hallopeau, Du Castel, Feulard, Jacquet, and Pringle, are: Epithelioma Arising from a Lupus Scar; Erythema Iris. Erythema in Concentric Circles. Hydroic Erythema. Hydroa Vesiculæ of Bazin; Lichen Planus of Wilson, of the Papulo-Erythematous Variety; Biskra Button.

In addition there are several woodcuts. We have repeatedly endeavored to express how completely this work deserves the fullest praise.

## Correspondence.

### LONDON LETTER.

By RAYMOND CRAWFURD, M.A., M.D.

We have now in our hands the Report of the Departmental Committee appointed by Lord George Hamilton in November last to inquire into the health of the British Army in India: its findings are simply appalling.

The main features of the Report may be summarized as follows: In 1889 a Cantonment Act was introduced into the Indian Army Service, which established a Lock Hospital system in dealing with venereal diseases. While the Cantonment Act was in force there was a marked decline in the amount of venereal disease, but since its abolition in 1893 there has again been a rapid increase, and this coincidentally with a steady decrease in disease assignable to other causes. In 1895 the figures had reached their maximum, and showed an average of victims amounting to 522.3 men per 1000 strength. In the words of the Committee: "It is responsible for more than one-third of the total sickness, and the constant and complete disablement of 3200 men out of a force of 71,000, and a vast amount of partial disablement and invaliding under the head of many other complaints."

Out of the 5882 men detailed for field service with the Chitral Relief Force, close upon 12.5 per cent were found unfit for active service; and at this ratio 8800 men out of a total force of 71,000 would have to be put down as useless. The visit of the Committee to the Military Hospital at Netley, where soldiers invalided from India come under medical treatment, only served to fill in the details of this terrible picture. "In many cases," the Report runs, "recovery is hopeless, and what to do with them has become a question of serious difficulty: their friends refuse to receive them. Death alone can solve the difficulty and release them from their sufferings." Nor is this the end of the evil, for as these men return from India they are the means of importing a constant supply of venereal disease for dissemination at home. Surely it is strange that while we take no steps to prevent the inroad into our hearths and homes of a foul pestilence that by slow ravages eats up body and soul alike, we appoint commissions and hold conferences for keeping at bay a

disease which probably can never get foothold on our shores under existing sanitary conditions, and is at any rate merciful in the rapidity of its devastation. The Report further draws a comparison with the statistics of venereal disease in other European armies, where special regulations are in force. Thus the ratio per 1000 strength of men incapacitated is in the German Army 27.3; in the Russian, 43; in the French, 43.8; while in our own army it is 203.7 at home, and 438 in India. How to deal with this appalling catalogue of disease is the question with which we are now brought face to face. These figures do not serve to show any increase in sexual immorality, for on all hands it is agreed that with the better care bestowed on the British soldier in the last few years the actual standard of morality has been considerably raised.

stand a dose of microbes that would under normal conditions be fatal. About twenty-four hours is necessary for the development of this condition, and its duration is about four days. This heightened resisting power is quite distinct from specific immunity, for injections of indifferent substances produce the same conditions in a lower degree; then an injection of normal saline solution markedly increases the resistance of the animal to microbial agencies; also the immunity is of a more or less transient character, while specific immunity tends to be more abiding in its influence. The following table from Mr. Durham's experiments deserves careful study; the infecting agent was typhoid bacilli, the animals rabbits, and the preliminary doses of one cubic centimeter were given twenty-four hours before infection:

No.	Previous Treatment.	Infected with	Result.
1 .....	None.	4 loops.	Death in under 17 hours.
2 .....	None.	3 loops.	Death in 9 days 22 hours.
3 .....	1 per cent. NaCl.	4 loops.	Recovered after illness.
4 .....	Typhoid serum (horse).	6 loops.	Recovered: hardly ill.
5 .....	Typhoid serum (horse).	9 loops.	Recovered: hardly ill.

We have rather to deal with a vastly increased liability to disease; and while we are quite in sympathy with those who would strike at the root of the evil by educating the moral discipline of our soldiery, we are equally aware of the tardy nature of such a method of redress, and press for immediate measures to grapple with the evil before it gets out of hand. Our own wish would be to renew the Cantonment Act and enforce it rigorously, or if we must yield to fanatic morality, let us at any rate respect the dictates of reason and treat it as we treat other diseases that endanger the health of the community.

One of the most interesting features of this month has been a communication by Mr. Herbert Durham to the Royal Medico-Chirurgical Society of some experiments on peritoneal infections, which should possess an important clinical bearing on transperitoneal operations. These experiments were in continuance of similar work by the German bacteriologist Tsaëff in 1894 in connection with the cholera vibrio. Tsaëff showed that several different substances, when injected into the peritoneal cavity of guinea-pigs, were capable of affording protection to the animals, which were inoculated with cholera vibriones upon the following day. These preliminary injections raise "the power of resistance of the part," so that it can with-

This table serves also to emphasize the essential distinction between heightened physiological resistance and specific immunity. Similar experiments with the cholera vibrio and other bacteria gave similar results. This condition of increased bactericidal power of the peritoneal fluid is associated with the appearance in it of a number of active phagocytes of two kinds: (1) finely granular oxyphil or polynuclear leucocytes or microcytes; (2) macrophages. As Mr. Durham remarks, the point of practical therapeutic importance is as to whether such preliminary injections into the human subject prior to operative interference with the peritoneum would similarly heighten the resisting power of the subject. Owing to the limited duration of the protection the method could never replace existing precautions against sepsis. Moreover a difficulty suggests itself in connection with the choice of injection, for the frequency of occurrence of any individual micro-organism is not so constant and invariable as to suggest the injection most likely on *a priori* grounds to have the greatest effect. The point to be aimed at is "to produce an ample leucocytosis in the peritoneal fluid, and also if possible to give a super-added specific protection by aseptic means." Statistics do however point to a relative frequency of streptococci in infective peritonitis,

and it might be desirable to employ anti-streptococcic serum. In England much too great stress has been laid upon the importance of bacillus *coli communis* as the prime factor of infection in cases of intestinal origin. This is partly due to its vigorous growth obscuring the feeble growth of other micro-organisms, but also to the fact that some observers have used carbolized culture media, on which few microbes but bacillus *coli* are capable of growing; in fact the bacillus *coli*, though undoubtedly pathogenic in man, is probably one of the least virulent organisms present in septic peritonitis. Examination of the peritoneal fluid alone is quite insufficient in such cases, as this may be absolutely sterile, while the omentum and other peritoneal membranes harbor innumerable microbes; and the search should be carried even further afield than this to the lymph-channels and glands connected with the peritoneum, and to the blood. The most important lymph-channels are those which pass up through the anterior mediastinum, and these should always be carefully examined in every case of peritonitis, as this is the path by which bacteria pass from the peritoneal cavity into the blood. In most cases of acute septic peritonitis there is a remarkable absence of signs in the peritoneal cavity, and unless a wider examination be made death from sepsis is likely to be attributed to shock. As a general rule, the least acute processes are those that manifest the most obvious signs in the peritoneum. If then we use antistreptococcic serum rather than one of the less efficacious indifferent injections, of which nucleinic acid seems to be the most active, we secure not only heightened resistance, but specific immunity as well in the great majority of cases. The fact that the omentum is so prone to harbor micro-organisms has an important bearing on the method of flushing the peritoneal cavity in cases of suppurative peritonitis. To quote Mr. Durham's own words: "In the laboratory and in the post-mortem room it is found that the majority of organisms and exudation cells are found about the omentum, the surfaces of the liver, spleen, and diaphragm—in fact the upper part of the peritoneum. It seems clear therefore that in cleansing the abdominal cavity especial attention should be paid to thoroughly mopping out and washing these parts—the omentum, and between the liver and diaphragm," not however to the exclusion of other parts. Intestinal peristalsis by the vermicular movements seems to be the

mechanism which determines deposit on the omentum; here they are brought into intimate contact with the leucocytes that transude chiefly from the mesenteric vessels. From this Mr. Durham draws an argument in favor of laxatives in septic peritonitis, for by such means peristalsis is re-established, and the increased circulation in the mesenteric vessels favors increased local leucocytosis. We have dealt very fully with Mr. Durham's paper, as the suggestions it contains are so well worthy of close attention and further investigation.

Mr. Clement Lucas's indictment of anesthetic apparatus as a purveyor of disease has at any rate been fruitful in stimulating criticism. We ourselves are rather of opinion that Mr. Lucas has grappled with a phantom in maintaining that the pulmonary sequelæ of operation are to be attributed to infection and not to the anesthetic. It has been generally held that the presence of the pneumococcus in the lung is not in itself sufficient to cause pneumonia, but that some factor lowering the physiological resisting power of the part is necessary for the effectual activity of the micro-organism. The pneumococcus has been shown to be present in the sputum and in the discharges from the respiratory passages of a very large number of persons in health. In operations this factor is almost beyond reasonable doubt the anesthetic. So it is that pneumonia is much more frequent after inhaling ether and chloroform than nitrous oxide, because the last named is much less irritating to the lung. In all probability the apparatus has no calculable influence in its production, for nitrous oxide, which necessitates the most elaborate paraphernalia, is seldom or never followed by pneumonia, while the same cannot be said of chloroform, which is usually administered on a receiver saturated with the drug; and in this connection it should be remembered that chloroform is a powerful antiseptic, while nitrous oxide is a relatively powerless bactericide. Still, while even an infinitesimal opening for infection exists, it is of something more than mere academic importance to forestall this possibility. With this end in view Dr. Silk of London has introduced celluloid and metal inhalers, which can be submitted to all the same processes of sterilization as are applied to other instruments used at operations; or, as suggested by Mr. Lucas, toughened glass might be employed for the same purpose, and an asbestos web that could be raised to a white heat substituted for the flannel or sponge receiver.

## PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

At a dinner given some days ago by the Society of Hygiene of France, one of those called upon to speak was Dr. C. E. Sajous, of Philadelphia, who referred to a remark made not long ago during a discussion in the Chamber of Deputies on the practice of medicine in France by foreigners. One of the deputies, Mr. Georges Berry, had said that it was a well known fact that in Philadelphia any one could purchase a diploma. Dr. Sajous recalled the case which had been the ground of such erroneous statements, namely, that a certain Buchanan, having by fraud obtained possession of a charter, had sold so-called diplomas to foreigners in some instances. This man, prosecuted by the Philadelphia County Medical Society, had been arrested and sentenced to a term of years in prison, served his term, and had already been dead some years. Though the prosecution occurred some seventeen years ago, Dr. Sajous expressed his astonishment to find that it had not as yet reached foreign ears.

Dr. Sajous also spoke of the numerous institutions of learning to be found in Philadelphia and the United States in general, and expressed his belief that taken all in all they could favorably compare with the majority of European institutions. It was greatly to be regretted, he thought, that the United States should be so unjustly criticized, and he sincerely hoped that the statement made by him would be sufficient to modify the false impression under which foreign physicians were laboring.

The physicians present, many of whom are very prominent, expressed their hearty approval of Dr. Sajous' statements on behalf of his country's institutions, and stated that all present would do all in their power to counteract the false ideas existing on the subject among the profession of the Continent.

In "*Les Misérables*," by Victor Hugo, the author speaks of Louis Philippe, who reigned in France from 1830 to 1848, as "the first King who ever shed blood to save life." These words refer to an incident in Louis Philippe's life of which the Duke of Aumale, his son, recently spoke. The King in 1833 went out with his entire family to meet his son-in-law, the King of Belgium, who was coming to Paris. An old courier who accompanied them was thrown from his horse and injured. The King called for some one to bleed the man (we must remember the medical theories

of the early part of this century), and as no one offered to do so, himself opened a lancet which he had with him, tore up some handkerchiefs, and bled him. This lancet, according to the Duke of Aumale, his father had retained from the period when he had acted as Dresser in the Hôtel-Dieu of Paris.

The Duke of Aumale stated that he could remember seeing a painting made at the King's order in which the latter was shown in the white apron worn by the dressers, and accompanying the head of a medical or surgical service in the visit to one of the wards of the Hôtel-Dieu of Paris.

On Saturday, March 24, there died at Havre a physician—Dr. de Bossy—who for many years had been the oldest medical man in France, and perhaps of the entire world. He had just finished his 104th year. He was born in Paris in 1793, was taken to England, where his youth was passed and where he pursued his medical studies. After obtaining his diploma he sailed for India, where he practiced ten years, and later on in the Mauritius. In 1843 he returned to France, passed his Doctor's Thesis at the Faculty of Medicine of Montpellier, and settled in Havre, where he practiced as long as he lived, for until the very end Dr. de Bossy continued to receive patients and to make visits. A celebration was given four years ago by his colleagues in honor of his 100th year. Dr. de Bossy's father lived to an even greater age—108 years.

Recently Dr. Dieulafoy has described in various communications made to the Academy of Medicine and other societies, an affection to which he has given the name of Intestinal Lithiasis. This affection, which may be found in patients of all ages, consists in the expulsion by the anus of sand or even of concretions of larger size. Almost always it is associated with muco-membranous colitis. The sand is in some cases voided without pain by the patient, who may even not know of the existence of the phenomenon, until by chance he discovers it. In other cases severe attacks occur, during which colic, nausea, and even vomiting, similar to the symptoms of hepatic colic, are present.

It is probable that this intestinal lithiasis is allied to the gouty diathesis.

In one case analysis of the sand gave the following results: Fatty substance, 28.50 per cent.; calcium phosphate, ammonio-magnesium phosphate, and calcium carbonate, 16 per cent.; chloride, traces; animal substance and organic matter, 55.50 per cent.

As the proportions vary, the sand and gravel found in various cases may differ in color, friability, and hardness. Dr. Dieulafoy calls especial attention to the fact that as yet he has seen no case of appendicitis connected with this affection.

The treatment recommended is the same as that in biliary lithiasis.

In France baldness, and especially premature baldness, has been considered one of the symptoms of the arthritic diathesis. In a recent series of researches Dr. R. Sabouraud proves, to use his own words, that it is "one of the most extraordinary and purely microbial affections to be met with." Dr. Sabouraud, who for several years has been connected with the St. Louis Hospital, the great dermatological hospital of Paris, and who is at the head of the Laboratory connected with the service of Dr. Fournier, is the same whose researches on the parasite of trichophytosis are now universally known.

Ordinary baldness is due to a specific microbe which invades the hair follicles. This microbe he has succeeded in cultivating. Its action on the hair follicle may be summed up as follows: It first gives rise to hypersecretion of sebum followed by hypertrophy of the sebaceous glands annexed to the hair; this in turn causes progressive papillary atrophy, and finally the death of the hair. In other regions where excessive seborrhea exists, the skin is hairless, and treatment of seborrhea of such regions will tend to produce a growth of hair in places where previously none existed.

#### *A CASE OF ACETANILID POISONING.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: The following case of poisoning by acetanilid seems to me of interest. A married woman, aged twenty-one years, just two weeks after her confinement suffered from quite severe frontal headache and was given by a physician half an ounce of acetanilid in bulk in an envelope, with directions to take a small quantity of it on the end of a teaspoon every two hours. The patient took two doses as directed, and a few hours afterward, the headache still persisting, she concluded that a very large dose would be more efficacious, and swallowed a teaspoonful of the drug. Half an hour afterwards she began to grow weak and to feel dizzy, and an hour later she fainted and passed urine involuntarily. Her husband then consulted a book on Homeopathic Home Remedies, but failed to give her any relief.

She became cyanotic, and the husband becoming greatly alarmed sought for the nearest physician. I reached the case at 7 P.M. and found her in a semi-conscious condition. The pulse was slow and extremely feeble, the respirations slow and shallow, the forehead bathed in sweat, the face livid and perfectly expressionless. The tongue, lips and fingernails were intensely cyanotic and almost black; the head, hands and eyelids were cold, but her feet were quite warm; temperature was normal; there was tingling of the skin over the entire body and some slight mental confusion. Some headache still persisted. There was suppression of urine until noon the next day, and when passed it was of a dark brown color and very abundant. I also noticed a loud and continuous borborygmus. The milk secreted by the breast was very much thinner than it had been before the poisoning. The cyanosis lasted for several days.

The treatment was essentially that advised by Professor Hare. The patient was forced to maintain a recumbent position, the head was kept low, and a hypodermic injection of aromatic spirit of ammonia followed by sulphate of strychnine and sulphate of atropine were given. Hot bottles were placed about the body, and she received  $\frac{1}{4}$  of a grain of strychnine every three hours by the mouth, alternating with whiskey and aromatic spirit of ammonia. Owing to the condition of the milk it was not considered wise for the patient to continue nursing her child, as the milk failed to return to its normal condition after recovery, and the patient was much exhausted.

Yours truly,

G. BARINGER SLIFER, M.D.

PHILADELPHIA.

#### *TAKA-DIASTASE.*

To the Editor of the THERAPEUTIC GAZETTE.

In the course of recent experiments I was accidentally led to find that Taka-Diastase is a very active peptonizing agent, being especially vigorous when brought in contact with the caseine of milk.

Having neither the time nor the facilities to pursue the matter further, I bring it to your attention, hoping that a careful investigation will be instituted.

So far as I know this is the first time that such a property has ever been attributed to a diastatic ferment.

Very truly yours,

J. B. RUSSELL.

### SOME OF THE UNTOWARD EFFECTS PRODUCED BY THE ADMINISTRATION OF THE BROMINE COMPOUNDS.\*

BY H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

It is not my intention to discuss in this paper the well known untoward effects of the bromides as they are manifested by eruptions on the skin, mental torpor, and the final de-

velopment of a cachexia and general as well as nervous feebleness. The conditions on which I desire to dwell are more unusual and not so well known to the profession, although they are more common than would be supposed.

In the study of remedies, both old and new, the tendency of the physician is rather to record his successes than his failures, and to report the instances in which the drug has done good rather than those in which it has failed or done harm. It is only after many years of experience roll by that the profession gains a complete view of the reverse of the therapeutic shield.

The untoward or unexpected effects of

\* A paper read before the Association of American Physicians, May, 1897.

drugs are, however, never to be forgotten, and the possibility of a remedy causing an unusual symptom is to be ever borne in mind.

At a meeting of the Association of American Physicians held in Washington in May, 1896, Weir Mitchell read a paper detailing a number of instances in which the use of the bromides had speedily produced a number of untoward effects over and above the skin eruption, disordered digestion and mental slowness usually met with after full doses of this drug are used. Thus the symptoms manifested consisted in great irritability of temper, moroseness, and homicidal or suicidal tendencies. In one case, that of Jacksonian epilepsy in a child, imbecility developed from the use of bromides; another child became a sufferer from amnesic aphasia; and in an adult female suicidal tendencies and melancholia appeared when the drug was used and disappeared when it was stopped. Voisin and Stark reported cases many years ago, and Harriet Alexander as recently as July, 1896, has contributed a valuable paper on this topic, in which she reviews the literature on this subject in this country quite thoroughly. Seguin reported the case of a twelve-year-old boy who had *petit mal* in the form of chills, and when these were stopped by the bromides he became unmanageable and boisterous. Hughes of St. Louis has reported another case of *petit mal* which developed kleptomania when the bromides were given, and Rockwell has recorded an instance in which an epileptic female on taking the bromides became irritable and suspicious. Dr. Alexander in the paper quoted cites several instances from an earlier contribution of hers on this subject. An epileptic nymphomaniac always became irritable and suspicious on the use of the bromides. In another woman, with a family history of epilepsy and imperative homicidal conceptions of long continued form, erotico-religious, auditory and visual hallucinations followed the use of the bromides. In another female troubled by coprolalia the bromides caused sullenness, and unrestrained coprolalia. In still another case the bromides caused an irritable suspicious state in which the patient became treacherous. A ten-year-old girl with procursive epilepsy had three attacks replaced by irregular kleptomania attacks, and she became suspicious and irritable. The last three cases reported by Alexander are particularly interesting. They are as follows:

A female; has *petit mal*. She denies all epilepsy. Long after her marriage, epilepsy,

although it clearly existed, was never suspected until she awoke her husband one night by beating his face with a slipper while unconscious. In the inter-epileptic period she is mild tempered, good humored, and suave. Under the bromides she becomes first irritable, and querulous during the inter-epileptic period, then paroxysmally furiously excited, and has vivid auditory and visual erotico-religious hallucinations and is coprolaliac. Mixed treatment has no such effects.

Since then Alexander has observed the following cases:

A thirty-four-year-old woman had *grand mal* followed by a dazed condition. Under the bromides these attacks were replaced by nymphomania with decided erotic manifestations, attended by religious hallucinations and furious masturbation. The use of ergot removed these manifestations, and the alternation of ergot with the bromides prevented them.

A forty-two-year-old woman had attacks of *grand mal* at the menstrual period and *petit mal* in the interregnum. These were both replaced by furor under the bromides.

Similar instances have been reported by Janeway, Dana, and Draper, and the older literature of medicine shows that these unusual effects were not unknown and are not now met with for the first time. Many years ago Hammond recorded the case of a gentleman to whom he gave at first fifteen grains of potassium bromide three times a day. These doses, which were slightly increased, soon produced symptoms of mental aberration, which disappeared when the medicine was stopped. Later the patient of his own free will insisted upon taking as much as one ounce of the drug a day. He developed marked insanity, delusions of persecution, and the delirium of grandeur. He became timid and cowardly, and finally so insane as to necessitate his removal to an asylum, in which recovery took place. In other cases hallucinations as to sight or sound have come on without there being any alcoholic history to complicate the case.

Bannister has also reported a condition of pleasurable intoxication with exaltation of mind after doses of bromide. Thus he reports the case of a man of thirty-six years of age who was a sufferer from frequent epileptic attacks and had slight mental impairment, but no true psychic disorder and no delusions. He was regarded as a quiet, well-behaved patient, except when the bromides were given him, when he became furiously

excited and unsafe. Thus before commitment to an asylum he had been convicted of homicidal tendencies. Small doses of the bromide rarely brought on the attacks except after several days, but as much as one and a half drachms daily made him unmanageable in three or four days. Stopping the bromide stopped the mania but allowed the return of the attacks. Bannister reports other cases, three in all out of twenty-one epileptics under his care. This and the following report of cases illustrate the clinical fact that the arrest of epileptic attacks by full doses of the bromides produces on rare occasions evidences of nervous excitation in other forms. Thus Baker in the *Medical Register* of December 8, 1888, reports the case of a male of eighteen years suffering from many convulsions each day who was said to be unable to take the bromides. Nevertheless he was put on fifty grains a day. This resulted in an arrest of the attacks, but they were supplanted by noisy outbreaks of ungovernable rage but no delusions. Another case of a young man was met with who had maniacal delusions which always disappeared if the bromides were stopped and the attacks allowed to return. A third case experienced mental confusion when the bromides stopped the attacks. Lepine also reports a case (*La Semaine Médicale*, Dec. 23, 1891) of a tabetic young woman who received sixty grains of bromide a day for convulsive attacks. In the course of a few weeks she became progressively weaker and delirious; and Lepine believes that difficult speech, delirium, and mental weakness often follow the use of bromides.

Holmden in *The Lancet* of October 18, 1886, also reports the case of a sailor aged thirty-three years who was in the habit of taking three drachms of bromide of potassium a day for the purpose of relieving insomnia, and who began to develop delusions and to be unable to collect his thoughts. Notwithstanding advice to the contrary he persisted in the use of the drug and developed delusions of persecution, maniacal symptoms, and suicidal tendencies, followed by great prostration. Recovery ultimately occurred.

Hameau (*Journal de Médecine de Bordeaux*, March, 1868) has reported the case of a young woman of twenty-two years who after taking no less than four and a half pounds of bromide of potassium in ten months developed cachexia, delirium, and after great prostration she died.

We have also the report of Eigner in the *Wiener Medicinische Presse*, Nos. 25-34, 1886, who records the case of a woman who took five pounds in a year, and after developing the ordinary symptoms of bromism developed tremor, a staggering gait, followed in a few hours by excitement passing into delirium with delusions of poisoning.

Thompson in *The Lancet* for May 11, 1889, asserts that he has frequently seen cases of maniacal insanity produced in feeble-minded persons and in the insane by drenching them with bromides. He does not, however, report any definite cases.

Gaston Lyon in his "Traite Elementaire de Clinique Therapeutique," 1895, says in some cases the bromides have to be stopped when given to epileptics as they either increase the number of the attacks or, if they stop them, bring on cerebral disturbances.

Marked untoward effects of the bromides are recorded by Soullier ("Traite de Therapeutique et de Pharmacologie," Paris, 1895), who states that in those instances in which a bromide cachexia develops there is in addition to feebleness commencing paralysis of the lower extremities, tremors, coldness, anorexia, and diarrhea, loss of intelligence and memory, and sometimes delusions, hallucinations, headache of an intense kind, and dilatation of the pupils. He quotes Le Gendre as having seen instances in which the bromides in overdose caused in epileptics symptoms simulating typhoid fever.

Laborde (*Gazette Médicale de Paris*, 1886) has seen sexual excitement follow the bromides, and Winters has reported visual hallucinations (*New York Medical Journal*, 1883). Alexander also quotes Kiernan and Monroe (*Medical Standard*, 1887 and 1891) as having met with cases of aphrodisia from this drug.

One conclusion seems certain beyond doubt, that in many cases of epilepsy the bromides are very capable of causing grave injury aside from the general depressing influence which they excite in all persons if given in full doses for any length of time.

In other instances in non-epileptic patients the use of the bromides has produced aphasia and apyrexia. Thus Lockhart Clarke has recorded an instance of a patient who said "contraction" for "subscription," and E. H. Clarke one who called a buckwheat cake a comb and a comb a buckwheat cake.

With the idea of gaining additional information about such important variations from the usual manifestations of the action of the bromides the writer addressed the following

letter to a number of well known neurologists and to physicians in charge of insane asylums:

DEAR DOCTOR—Within the last few months my attention has been called to the fact that the administration of bromide of potassium to certain persons, either sane or insane, produces a mental alienation, or influences unfavorably the manifestations of insanity already present. I am trying to find out whether the experience of one or two gentlemen has been duplicated by others having such a wide experience as you must have had. I enclose a set of questions designed to elucidate this point, and shall feel personally obliged to you if you will be good enough to answer as fully as you feel inclined the questions that I enclose.

The questions were as follows:

1. Have you noticed in your practice that the administration of the bromides in full doses ever produces mental alienation or true delusions?
2. If so, have the symptoms of the patient been those of sedation or excitement?
3. Has a single full dose ever produced such symptoms?
4. Do you think that such untoward effects of the bromides are more commonly met with than is generally thought?

The answers I have received are as follows as to Question 1:

Dr. H. M. Bannister, of the Asylum at Kankakee, Illinois: "I have seen epileptics who were rational and quiet made violently maniacal. This was directly induced by the bromides. I have also seen pronounced hebetude and mental depression caused by their use. As regards the production of true delusions by the bromides I cannot speak definitely any further than to say that I believe the causeless violence and the deep depression are both probably attended with false conceptions."

Dr. John B. Chapin, of the Pennsylvania Hospital for the Insane, Philadelphia, answers Yes; that he has seen mental alienation and true delusions follow the use of the bromides, and in an article by this author read before the Association of Medical Superintendents of American Institutions for the Insane in 1891 he records a number of cases closely allied to those under discussion in which the use of the bromides with other drugs such as chloral and morphine produced delusions or maniacal excitement. Thus in one case a man was brought to him with "acute maniacal fury," who had received fifteen grains of bromide of potassium every three hours for a time not stated, and chloral twice a day. The symptoms ceased when the drugs were stopped.

Dr. E. N. Brush, of the Sheppard Asylum of

Maryland, states that he has seen "in many instances mental confusion ranging from simple hebetude to low, muttering delirium induced in epileptics by the administration of bromides, conditions which have cleared up when the drug was stopped." He also says: "It is very common in institutions to receive cases, clinically very much like what has been described as confusional insanity, in whom either depression or melancholia predominated complicated by restlessness and excitement, sometimes conditions simulating delirium tremens, who have rapidly cleared up and made a good recovery when the bromides were discontinued and full diet, attention to disturbed digestive functions, often aggravated by the use of bromides, and ferruginous tonics have been administered. It is very easy to appreciate the reasons for all this. The patient at home has been restless and excited, as the result of mania or of melancholia with apprehension, and sleepless, as is almost always the case in the various forms of alienation in the acute stages. The family physician has naturally endeavored at the same time to quiet the patient and allay the worry and anxiety of the family incident to the patient's restlessness, and has considered the bromides as the best therapeutic means to accomplish these results. Much of this has grown out of the unfortunate teaching of a few years ago, as a result of which very many practitioners have the idea that all forms of insanity depend upon cerebral hyperemia and that bromides in one form or another have the property of controlling this and producing sleep." He cannot recall a single instance in which mental alienation or true delusions followed or was apparently caused by bromides if the patient was of sound mind before the drugs were given.

Dr. Richardson, of the State Asylum at Columbus, Ohio, in an experience of over twenty-five years and 6000 cases cannot recall an instance in which the bromide has caused insanity in a previously sane person.

Dr. James G. Kiernan, of Chicago, answers this question in the affirmative, and adds that it should be understood that he refers in his replies to the untoward action of potassium and the alkaline bromides on the sane, exclusive of epileptics.

Dr. W. Brown Ewing, Physician of the State Asylum for the Chronic Insane at Wernersville, Pennsylvania, says he has not met with any disagreeable symptoms.

Dr. John W. Ward, Chief Physician to the New Jersey State Hospital for the Insane, re-

plies as follows: "I take it for granted that you mean the bromides of potassium and sodium especially, and in reply, first, I would state that we have never had any symptoms of mental alienation following full doses of the bromides. We have used the bromides and particularly bromide of potassium in large doses for the last twenty-five years in this institution. We give it nowadays almost always to epileptics—at least, we regard it as the best remedy, either singly or in combination, in the cases of epilepsy that come under our care. The only ill results we have noticed in this hospital is a breaking down of the system as manifested by disordered digestion and pimples on the face where there is long continued use. This we have often obviated by associating the bromide with tonics in its exhibition—not always, but usually so—so much so that in nearly all, or quite all, the cases where now we propose its use for a continued period we associate it with tonics. Apart from this, however, we have never noticed any injurious effect following its use, even when giving twenty-five and thirty-grain doses three or four times daily for a period of months. I may state, however, that I have seen decided symptoms of dementia, in a few cases, follow the use of chloral hydrate. It occurs to me that this is possibly the case in the instance mentioned by your friends to which you refer. Where mental alienation has followed the use of the bromides, they may have been exhibited in association with chloral, as seems to be the fashion now in some sections. Under no circumstances do we ever administer chloral and bromides of potash or soda together. We have not infrequently had cases brought to us described as having the bromide habit, but in each and every case I have found that morphia was associated as a quieting agent with the bromide, and in such cases the morphia habit did exist, but the bromide habit did not. After exhibiting the bromides for months, we have been able to withdraw it at once without any evidence of any particular habit having been formed for it, or in any craving after the drug. When the bromide of potash was heralded in our magazines as a remedy for the habit of masturbation I gave it in large doses, with no bad effect following it, except in a few cases where it produced so-called bromide intoxication. This followed the exhibition of the drug in sixty-grain doses four times a day for several days in succession, with no particular benefit so far as the habit was concerned, but with a

decided muscular weakness and trembling and inability to walk, and in a few cases inability to co-ordinate the movements, much the same as in progressive locomotor ataxia. In each and every case, however, where such a result obtained, the patient soon rallied and regained his usual ability to walk in a few days after the exhibition of the drug was suspended."

Dr. H. A. Hutchinson, Superintendent of Western Pennsylvania Hospital for the Insane, Dixmont, Pa., says: "In answer to your letter I may say that I have never noticed any peculiarity in a patient following the administration of bromide other than the depression which is seen where it is pushed for a long time. I have never seen any delusions or other symptoms produced. We use but little bromide in this institution, almost none at all, and for years past my experience with this drug has amounted to almost nothing."

Dr. H. E. Allison, Medical Superintendent of the Matteawan State Hospital at Fishkill Landing, New York, says: "We seldom administer bromides in full single doses except in cases of great mental disturbance or in epileptic status. There are some few cases of epilepsy now which are receiving the bromides regularly in doses varying from thirty to sixty grains a day (ten to twenty grains three times daily). In occasional instances we have prescribed the mixed bromides. We have not noticed any mental alienation or true delusions which we could directly ascribe to the influence of this drug used in this manner.\* It is true that many epileptics possess delusions and that many pass into states of dementia; but these conditions arise irrespective of the use of the bromides, as there are certain patients here who possess delusions and who have not been put upon the bromide treatment. We have had one or two cases of bromism from the prolonged use of the drug, evidenced in the acne and in the dull, lethargic state of the patient."

Dr. Robert H. Chase, of the Friends' Asylum for the Insane, Frankford, Philadelphia, says he has seen the effects asked about in Question 1 and cites the following case: "Several months ago I was asked to see a young man, with view to having him placed in the Asylum. He was an epileptic, who had been taking the bromides under the direction of a 'traveling physician' who lived at a distance. When

\*In non-epileptic persons Dr. Allison has however seen excitement follow the bromides. See his answer to Question 4.

I saw him he was in epileptic furor, irritable and excitable, with persecutory delusions. I directed them to discontinue his medicine and ordered him to Atlantic City, where he rapidly regained lucidity and composure."

Dr. G. Alder Blumer, of Utica, has not met with symptoms of excitement, but he asserts that much harm is done by the indiscriminate use of the bromides.

Dr. L. Pierce Clark, of Craig Epileptic Colony of New York, replies: "I have never found any delusions produced by the administration of full doses of bromide. The character of mental alienation that I have most frequently noticed is that of dementia."

In answer to Question 2 Dr. Bannister states that symptoms of sedation and excitement were both present. In epileptic cases the excitement was marked rather than depression.

Dr. Chapin replies: "Sedation, mental hebetude, and subacute delirium." But in the report already quoted he cites cases of excitement.

Dr. Brush evidently thinks the symptoms are those of sedation rather than excitement.

Dr. Richardson says that it decreases mental activity.

In answer to this question Dr. Kiernan says the types are as a rule those of exhaustion, resembling acute hallucinatory confusional insanity; sometimes they are stuporous; very rarely emotional and exalted.

Dr. H. R. Allison has not met with excitement after the use of the bromides, but has with sedation, for he says: "We have administered the bromides usually in combination with chloral, in large single dose, to cases suffering from a quick succession of epileptic seizures—that is, to patients who were in the *status epilepticus*—and in such cases we believe that we have produced beneficial results by its administration, as the seizures have ceased and the patient passed into a quiet state, emerging therefrom exhausted, but afterwards progressing to a state of consciousness and ordinary health."

Dr. Chase replies the symptoms have sometimes been those of sedation, sometimes of excitement: "All the effects that I have ever noticed from the administration of bromide have been of sedation."

In answer to Question 3 few gentlemen have met with a case in which a single dose of bromide has had the effect of producing mental disorder.

Dr. Kiernan states that he has seen stupor,

acute hallucinatory types, and emotional exaltation resembling hypomania.

Dr. John W. Ward says: "I have never seen any ill effects whatever follow the exhibition of single full doses, say sixty grains of the bromides. In most cases it is tranquilizing. Sixty grains, however, we regard as an exceptionally large dose. Our usual standard dose, either as a tranquilizing agent or as exhibited to our epileptics, is from twenty to twenty-five grains, and repeated not oftener than three times per diem."

Dr. H. R. Allison says: "I am not aware that a single full dose of bromide has in our instances occasioned excitement, as it is only when such conditions of excitement prevail that the drug is administered."

Dr. Chase has never seen such effects follow a single dose.

Dr. L. Pierce Clark states: "I have seen a single large dose of bromide produce temporary amnesia which in a measure simulated the more permanent dementia seen after its prolonged administration."

In answer to Question 4 Dr. Bannister writes: "Yes, decidedly so, when large doses are given; not often with moderate doses carefully used."

Dr. Chapin also makes the same statement in the report already quoted.

Dr. Brush says: "For years I have been decidedly of the opinion that the administration of the bromides is subject to abuse on the part of the profession and that untoward effects are much more common than is realized. . . . I have made it a point for fifteen years to call attention to the dangers incident to the careless administration of the bromides."

Dr. A. B. Richardson, of Columbus State Hospital of Ohio, believes that the bromides tend to produce an increase in the dementia and hasten the degenerative process in epileptics, and he is much opposed to the use of the bromides in insanity as he thinks it impairs nutrition and the blood.

Dr. Kiernan thinks these effects are common.

Dr. W. Brown Ewing says: "Have never noticed any bad effects from the bromides. When long continued I always give two or three drops of Fowler's solution, as in epileptics. My experience is that the insane do not show the rash as soon as the sane."

Dr. John W. Ward says: "An opinion based on our experience here would lead me to think, as has already been stated above, that no untoward effects ever follow the use of

the bromide, other than breaking down already referred to in answer to Question 1."

Dr. H. R. Allison makes the following interesting reply to Question 4, interesting because it to some extent modifies the view obtained from reading his reply to Question 1: "There is a condition of excitement which I believe is produced by the excessive use of bromides usually combined with chloral in persons who are not epileptics, but who are simply suffering from mental disturbance, constipation, and lack of nourishment, which often occurs in cases recently admitted. Histories in such cases often indicate that the patient has been systematically drugged with large amounts of both bromide and chloral, and that too little attention has been paid to other features of the disease, apparently relying upon large doses of sedatives to produce calmative results. By reference to our prescription list I find that there are but six patients out of a population of 575 who are at present regularly taking bromides, and the house is almost entirely free from exhibitions of noisy excitement."

Dr. Chase thinks the bromides are abused.

Dr. L. Pierce Clark: "I think that untoward effects of the administration of bromide are much more frequently produced than is thought by the profession at present, although at times it is difficult to say just how much mental alienation is produced by its administration because the epilepsy itself has a tendency to produce mental symptoms almost the same as those obtained from the administration of the drug."

In the discussion of Dr. Mitchell's paper in May, 1896, the author of this article brought up the question as to whether the depressant and other harmful effects of the bromides were in a certain number of cases due to the potassium base, and later discussed it in the editorial columns of the *THERAPEUTIC GAZETTE*.

Physicians are wont to look for all the influences exerted to the bromine rather than to the base, and yet when full doses of any one of the potassium salts are used a definite and well marked physiological action takes place in addition to that produced by the bromine, iodine, or other medicament ingested with the potassium; further, the effect of the potassium in large amount is distinctly poisonous to all protoplasm, and in small doses it acts as a depressant to important vital functions, and for this reason preparations in which sodium is the base are to be preferred. With these views, however, some

of those present when Dr. Mitchell read his paper did not agree, and Dr. Dana of New York went so far as to speak of the possibility of potassium exercising any depressant effect as a "bugaboo" unworthy of credence and never seen in practice, although the writer of this article asserted that he and other clinicians had noted this well known fact by the bedside.

If we regard the matter from a purely scientific basis we find that as long ago as 1867 Rabuteau, from his investigations, laid down the rule that the poisonous action of the metals increased with the atomic weight amongst the elements of the same group—so that potassium, the atomic weight of which is 39, is more poisonous than sodium, the atomic weight of which is 23. Again, if we take chloride compounds, we find that chloride of potassium is a muscle poison and that chloride of sodium is innocuous. The studies of Guttman, Ringer, Claude Bernard and others prove that "potash salts are all far more poisonous than soda salts," and that the acid of the salt plays no part in producing the poisonous symptoms in such salts as the nitrate, carbonate, and chloride; or, in other words, potassium is always a poison in itself. Full doses of the potassium salts, we are told by Ringer, lessen the frequency and force of the heart's beats and make them irregular, and again "that soda salts in twice or three times the quantity which proves fatal in the case of potash salts produce no effect on the system save a passing weakness." Even in still larger doses soda salts exert no influence on the heart or the temperature, or on the brain, cord, nerves, or muscles, whereas potassium does depress all these functions or parts. In regard to bromide of potassium Ringer states, after discussing the experimental evidence: "It produces the same symptoms, in the same order, as other potash salts, and the more or less rapid induction of these symptoms depends on the amount of potash the salt contains. Bromide of potassium, like the chloride, paralyzes not only the central nervous system, but likewise the nerves, muscles, and heart, sooner than the nerves, and the nerves sooner than the muscles; and therefore we conclude that these effects of bromide of potassium, which it possesses in common with all potash salts, are due solely to the potash, the bromine playing no part in the process."

Leaving the scientific side of the question, and turning to that of practical therapeutics,

we need only reiterate the fact that we have seen potassium salts in full doses produce depression, and quote from the New Sydenham Society's Translation of the Lectures on Pharmacology of Professor Binz, of Bonn. Thus, after detailing the symptoms produced by large doses of bromide of potassium in healthy young men, in whom there was a fall of temperature and feebleness of the heart, Binz says: "Control experiments with potassium chloride showed that the effect on the heart was always largely due to the potassium. Later on we shall have yet to consider in detail the very marked effects which the salts of potassium exert upon the heart's action."

And again Binz states: "Sodium bromide, taken by the same individuals in the same manner as the potassium salt, produced the same effects on the nervous system, but not on the pulse and temperature."

To quote once more from Binz: "If potassium bromide has been taken for a considerable time, or even for a few days only, by susceptible persons, it has been observed to affect the heart unpleasantly, the pulse becoming feeble, irregular and intermittent. This is doubtless due to the potassium, which, constituting thirty-three per cent. of the salt, may very readily, given in the large doses above mentioned and in a form so easily absorbable, exert its depressing influence upon the heart's action. *For this reason sodium bromide is preferred by many physicians.*"

Recently we are told in the London *Lancet* of April 4, 1896, that "the coroner for Middlesex held an inquest on March 26 on the body of a man whose death appears to have been due to excessive indulgence in what is usually considered to be a comparatively safe drug—namely, bromide of potassium. Suffering from neuralgia, he had been in the habit of taking this salt in doses of two to three drachms. The drug does not appear to have produced any of the usual symptoms of bromism, but may have caused the palpitation of the heart of which the deceased had frequently complained. During the night of March 23 he felt very cold, gave two deep gasps, and almost immediately expired. The medical practitioner who was sent for stated at the inquest that he found the deceased quite dead, his mouth wide open, the eyes half-closed, and the pupils somewhat dilated. A bottle containing the drug was on the table, and examination showed that it was pure bromide of potassium. The witness attributed death to failure of the heart's action

caused by taking the bromide. This case is interesting for several reasons. It proves in a marked manner the danger of taking any drug, however harmless it may be reputed to be, in large and repeated doses without the advice of a medical man. No doubt in this instance a medical attendant would have recognized the depressant action the salt was exerting upon the heart and would have discontinued its use. Even in the most modern works on therapeutics this danger is not mentioned, yet it is well known that all potassium salts cause 'depression, shown by diminished energy of contraction of the cardiac muscle, with final stoppage in diastole' (T. Lauder Brunton). As this bromide is constantly administered in large and repeated doses, the action of its basic constituent should always be borne in mind, and if signs of its depressant effect are observed its use should be abandoned, the bromide of some other base being selected if in other respects the action is beneficial. Many secret remedies for 'fits' contain this drug in large quantities, and it is evidently desirable that the public should be warned that their use is not unattended with danger."

We may conclude therefore that the bromides are not as harmless drugs as some have thought, and in some cases they are capable of producing maniacal delirium whether the patient be sane or insane.

Finally, if they are used the sodium preparations are to be preferred to those of potassium.

---

#### SOME NEW METHODS OF RESUSCITATING STILL-BORN AND FEEBLE-BORN INFANTS.

---

BY BEDFORD BROWN, M.D.,  
Alexandria, Va.

---

The causes of still-birth and feeble-birth are numerous and of a varied character. Among these may be enumerated ante-partum hemorrhage from placenta previa, or early separation of placenta; infection from variola, rubeola, or scarlatina; the action of ergot; uremic poisoning in eclampsia; long delay of fetal head in pelvic cavity; compression of head from instruments; breech presentations, compressing the cord; twisting of cord around the neck of fetus; actual disease of cord from syphilitic degeneration; certain diseased states of placenta.

For a clear comprehension of the pathology, peculiar features, and symptoms of still-birth and feeble-birth it is necessary to

divide the subject into three heads: the still-born, the feeble-born, and the dead-born.

Between all of these forms there is a marked distinction; and yet in certain respects they bear a considerable resemblance to each other. In the first place it is necessary that we should have a clear conception of what is meant by the term still-born. Does the term apply indiscriminately to a dead-born infant and equally to a mere feeble-born infant? The term is really applicable to neither condition, but to a state where all the vital functions are in a state of temporary suspension.

*Definition of Still-birth.*—The general features of the still-born infant present all the indications of suspended animation; but this suspension, apparently profound, is only temporary, and vitality can be fully restored by proper means. In the still-born no arterial pulsation can be detected. The vital functions of cardiac action, respiration, and it may be secretion, reflex action, sensation, nervous power of the great centres, the brain, medulla, and spinal cord, and vaso-motor system are in a state of temporary suspension. Here then is a very striking resemblance between the general features of the still-born and the dead-born, and the difference can only be ascertained by the observation of certain symptoms, and by proper tests.

In defining the difference between the two conditions I would make the following signs the groundwork of diagnosis:

In both conditions the vital functions are in a state of absolute suspension—in the dead-born, permanently; in the other, temporarily. Again, in the one the vital functions cannot be resuscitated, while in the other they can be restored. The general condition of the still-born infant bears an exceedingly close resemblance to that of actual death. The cardiac sounds are absent and there is entire suspension of the pulse; the muscles are perfectly limp and relaxed; the function of respiration is absolutely suspended; yet the vital spark is retained and capable of being restored to vigorous life.

*Definition of a Feeble-birth.*—I would define the feeble-born, which is often mistaken for the still-born, as a state in which there is only a partial suspension of the vital functions, as the function of circulation, respiration, sensation, volition, reflex action.

The cardiac sounds are barely perceptible; the function of respiration amounts to a mere occasional sigh, or gasp; the reflex functions of the cord are greatly impaired, and so are the functions of sensation and muscular or

voluntary action. The power of swallowing is usually absent; the pulse is so feeble as to be scarcely perceptible; the cardiac sounds are exceedingly faint and can be barely detected.

This is the feeble born infant. It is a state which we must not confound with that of the still-born. Then how shall we distinguish the dead- from the still-born? Not by the suspension of cardiac action, respiration, reflex action, voluntary action, the function of sensation, for there is absence of all these functions in both conditions.

For immediate purposes of diagnosis probably extreme reduction of temperature of the dead-born infant, the temperature rapidly falling to the standard of the surrounding atmosphere, constitutes our most certain test. The temperature in the rectum of the still-born may fall to a slight subnormal degree, say two or three degrees, but never to the extent of that found in the dead infant. The fetus has for nine months lived the life of an amphibious animal, and possibly from this cause after birth it can withstand a suspension of vital function longer than ordinary cases of asphyxiation.

The physicians of the London Association for the Rescue of the Drowned make a statement that after four minutes of immersion and asphyxiation the restoration of life becomes impossible. I am sure that I have seen the still-born infant, when there was complete suspension of cardiac action and respiration for a period of twenty or more minutes, resuscitated and developed into a healthy childhood. Indeed it is difficult to decide what length of time a still-born infant may remain in a state of asphyxiation and recover. And there is one all-important rule to govern us in the management of these cases which should never be dispensed with, and that is never to relax our well-directed efforts at resuscitation until the temperature in the rectum of the infant falls far below the normal, say ten, fifteen or twenty degrees below the normal standard. Then we may know that it has reached a degree incompatible with life. My rule of late years is to test the temperature in the rectum every two or three minutes. If that remains near the normal standard I have positive encouragement to persevere in my efforts; if it suddenly falls ten or fifteen degrees I then have assurance that the case is hopeless.

There is another sign which should govern us in discriminating between the dead- and the still-born, and that is the state of the pupil. In the dead the pupil is widely di-

lated, while in the still-born it is but little, if at all, relaxed.

*Treatment.*—In my obstetrical practice during the past six or eight years, in all cases of still-born and feeble-born infants under my care, I have experimented very carefully and made very accurate observations on the hypodermic method of treating these cases. I have found the subcutaneous medication the most prompt, certain, and successful method, both for the restoration of the still-born and feeble-born. I find it the most convenient, easy of application, and consumes less time than any other method.

The system of the still-born and feeble-born infant responds more promptly and energetically to subcutaneous treatment than any other.

The materials for treatment are always at hand and convenient. Of course these little creatures are incapable of swallowing either nourishment or medicine, and the chief and only avenues left are through the skin and intestines.

In all cases of still-born infants, whether the infant be dead or only still-born, my method is to insert in each arm by hypodermic syringe four or five drops of whiskey and a single drop of tincture of belladonna. If the infant is only still-born the nervous and circulatory system will respond quickly and promptly to the stimulant action. If the infant is dead beyond resuscitation there will be no response whatever. But if there is no response, or a very feeble response, I go still further by injecting a drachm or two of warm sterilized water under the skin, and about two drachms with a drop of aromatic spirits of ammonia into the intestines, and then await the result. In my experience if these measures fail to produce reaction, it constitutes a fair test of the existence or absence of vitality. If the temperature continues to decline in the body of the infant while these measures are in progress, we may rest satisfied that the vital spark has taken its flight.

The first indication of a response to the action of the hypodermic remedies in these cases of profound asphyxiation is very soon present after the hypodermic. The muscles of the eyelids contract, and the eyes, previously closed, suddenly open; then the respiratory muscles are brought into rapid action, the glottis is expanded, air is inhaled into the lungs and suddenly exhaled, forming the shrill cry of the new-born infant.

These phenomena illustrate to us the energetic action of the stimulants on the great

nervous centres, the brain, medulla, and spinal cord. Then follows the development of cardiac action and pulsation at the wrist, which were previously dormant. In these cases I always observed the development of reflex action in the respiratory nerves before that of cardiac action. Invariably following restoration of respiration there was development of cardiac action; they followed each other as cause and effect.

In cases of marked cyanosis I found subcutaneous injection of warm water at a temperature of 102° or 103° flushed the circulation, aided in the process of oxygenation, and stimulated the action of the heart and increased temperature.

I will give here the history of three or four cases for the purpose of illustrating the symptoms and treatment of the three varieties of condition treated of in this paper—the still-born, feeble-born, and dead-born.

CASE I.—After a very tedious labor with a rather contracted pelvis Mrs. W. was delivered of a still-born infant at full term. It was her first child, was a male, and all concerned were exceedingly desirous of its restoration. All of the ordinary remedies were brought into vigorous requisition without effect. The idea then occurred to me for the first time to inject whiskey under the skin. The infant had then been apparently lifeless for about twenty minutes. Six drops of whiskey were injected in each arm. It seemed to give no pain at the time, as the infant was perfectly insensible. But the response on the part of the great reflex centres was prompt and speedy. The eyes were thrown wide open; the muscles of the glottis contracted, expanding wide that opening; a deep inspiration and expiration followed; and the result was a shrill cry, and a succession of cries. Then the cyanosis cleared up and life was restored. I should have mentioned that in this case there were no cardiac sounds, no pulse, and absence of all respiration previous to the hypodermic.

This may be accepted as a fair example of a still-born infant treated by this method.

CASE II.—This case is related as an example of a feeble-born infant. At eight months' term Mrs. M. gave birth to this infant, which was so feeble that it could neither cry nor swallow. There were faint cardiac sounds, but no pulse was perceptible. There was considerable cyanosis. The respirations did not exceed ten per minute, and were exceedingly shallow, and the nervous system appeared insensible to impression. Six drops

of whiskey and one drop of tincture of belladonna were injected in each arm. This did not fail to develop reflex action. The respirations became more frequent and fuller. The action of the heart responded, the pulse became perceptible, and the cardiac sounds became more distinct; and after a reasonable time powers of deglutition were restored, at first feebly, then sufficient to swallow a few drops of weak milk punch, which was repeated every few minutes.

The subcutaneous injection of whiskey was repeated only once, and the infant was swathed in warm cotton-wool.

By continual care the infant was restored and grew to be a large, healthy child.

CASE III.—This was a case of a dead-born infant, and its history is cited here only to show the difference in the symptoms of the still- and dead-born infant. Mrs. F. at term gave birth to this infant after a tedious labor. In this case there was a partial placenta previa, and the mother sustained much hemorrhage. When the infant was born it presented the appearance of one made of white wax; it had evidently been drained of nearly, if not quite, all of its blood. There was entire absence of cardiac action, respiration, and a rapid decline of temperature after birth, and dilatation of pupils. Injections of whiskey and belladonna, of warm water, applications of dry heat, attempt at artificial respiration, all failed to produce the least response.

CASE IV.—Mrs. M., with contracted pelvis, was delivered after a very tedious labor, by forceps, of a dead-born child. In this case there was rapid decline of temperature in the rectum, which continued until it reached the standard of the surrounding atmosphere. Soon after birth the pupils were widely dilated. Respiration, circulation, reflex action, sensation, were all absolutely suspended. Various methods of resuscitation were tried in this case, as hypodermic injection of whiskey, application of dry heat, injection of warm water in the intestines, but without avail.

In past years I have fairly tested all of the usual methods in vogue for the resuscitation of the still-born and feeble-born infants, as artificial respiration, the rapid reversal of the body of the infant to upright and the reverse positions in the air, Dr. Le Bordis' late suggestion of alternate withdrawal of the tongue, immersing the infant alternately in warm and cold water; but I infinitely prefer the method of hypodermic treatment, and this

is to be followed by the application of dry heat. The application of dry heat may be made by means of the gum-elastic bag partly filled with hot water, over which a doubled blanket is laid, and on this the body of the infant is placed and the soft blanket folded over it. The hot-water bag generates ample heat around the infant to constitute an efficient incubator, and may be arranged in a few moments in the absence of a regular apparatus. If necessary, the hypodermics may be repeated as required while the infant is subjected to this artificial heat, until it regains the power of deglutition, when a drop each of aromatic spirit of ammonia, tincture of belladonna, and brandy may be administered in milk or tea until the circulation and temperature are established.

Some three or four years ago I published a paper in the *THERAPEUTIC GAZETTE* describing briefly the treatment of still-born infants as detailed in the present paper.

Further experiences in the observation and treatment of still-born and feeble-born infants has not only served to confirm my original opinions, but also to increase my knowledge of the pathology and the best methods of managing these cases.

The present paper embraces also a description of the pathology and treatment of that class of cases designated as feeble-born infants, which my former paper did not. It is well known to all obstetricians that a large proportion of feeble-born infants die sooner or later—some within a few minutes after birth, some within a few hours, and others after a few days. The continuance of life in this class of births depends on the maintenance from birth of cardiac action and corporeal temperature. If these important functions are neglected in the beginning the infant will in a majority of cases succumb. Hence the importance attached in this paper to the symptoms of the feeble-born, and to a positive and early line of treatment of these cases.

#### *FAULTY HYDROTHERAPY.\**

---

BY SIMON BARUCH, M.D.,  
New York City.

---

Despite its antiquity water has not obtained a firm footing in therapeutics; despite its marked clinical results it still requires to be brought to the attention of practitioners;

---

\* Read before the German Medical Society of New York, Feb. 1, 1897.

despite its espousal by the best authorities in ancient and modern practice and literature the average medical man is not familiar with its history, action, and merits. What are the reasons for this lack of appreciation of hydrotherapy existing in the medical man?

1. The difficulty of applying water systematically and with precision, arising from lack of facilities and the natural repugnance to water existing in the human mind.

2. The espousal of water as a remedy by empirics and ignorant laymen who have brought it into disrepute. (See *New York Medical Journal*, Oct. 26, 1895.)

3. The absence of instruction in hydrotherapy in the curriculum of medical schools. To this lamentable circumstance may be charged the ignorance of the rationale of the action of water and the unfamiliarity with its technique which are found among the majority of medical men.

In this article it is proposed to deal only with the latter, because it strikes the author as the chief obstacle to the recognition of water as a remedial agent. The indifference to a definite technique has rendered its application in the hands of many unsuccessful and discouraging.

The latter is the chief cause of the indifference of the profession. Failure is the sure result of inattention to details. As a physician must judge the value of a remedy by his experience, it followed that failure to achieve the results which the experience of others had led him to expect has brought this remedy into disrepute, the fact unhappily remaining unrecognized that not the remedy but its application was at fault.

To stem this powerful current of prejudice and opposition has been my aim for many years.

Water is so simple, so easily applied, that any one seems justified in using it, and yet I say with a full consciousness of the import of my words that no remedy in the entire materia medica demands a like judgment and care in its application.

The following incident may serve to illustrate this proposition and serve as a warning:

In February, 1889, I presented the first plea for the Brand method of bathing in typhoid fever before the New York State Medical Society. On the day preceding this meeting a now eminent teacher of medicine informed me that he never intended to use so heroic a remedy, because he had seen the able visiting physician of the hospital in which he had served as an interne "kill a

patient" by this treatment. Further inquiry elicited the fact that this so-called Brand bath consisted in wrapping the patient in a sheet, placing her on a Kibbé cot and sprinkling her with ice-water until the mouth temperature showed marked lowering.

A brilliant young man, then already a teacher and hospital attendant, was bitterly prejudiced against a method of bathing of which neither he nor his justly eminent teacher knew anything. Both regarded the lowering of temperature as the chief aim of the cold bath, and looked upon any mode of applying cold water as a bath, losing sight of the difference in effect arising from a difference in technique.

A glance at the true object and rationale of the cold-bath treatment of typhoid fever introduced by Ernest Brand will clearly show the difference in effect arising from a deviation from its exact technique. Typhoid fever is an infectious disease, producing in the human organism a toxemia which overwhelms the nervous system, upon whose integrity the functioning capacity of all the organs depends. Death is due to the failure of one or more of these organs to properly functionate. It has been definitely ascertained that high temperature, which tradition has raised into a hydra-headed monster, is not the chief danger in this disease. If the pulse, respiration, nutrition and the secretions could be maintained near their normal standards, high temperature, significant though it be as a symptom, may well be disregarded as a lethal factor. Hence, when the illustrious Brand devised the method of bathing by which thousands have been saved from certain destruction, reducing the mortality of typhoid fever to almost *nil*, he distinctly urged the profession to direct its main efforts to the sustenance of the nerve centres first, and to the temperature afterward. Although the latter was regarded as an index of gravity in most cases, the bath was not intended to combat it. A bath of 65° F., with friction for twenty minutes every three hours, whenever the body temperature reached 102.5° F., is calculated to arouse the nerve centres from their lethargy and give an impetus to all the dormant functions depending upon them. That a higher temperature of the water and prolongation of the bath would more positively reduce body heat is a fact well known to hydrotherapists, but it is a fact still unappreciated by the average practitioner.

The low temperature of the bath irritates the peripheral sensory filaments, from which

the irritation is conveyed to the central nervous system, to be reflected upon the heart, lungs, and secreting organs. Friction adds to the irritation by multiplying it, the cold water being kept in motion; cold affusion over head and shoulders is added to promote the same object. To whip up the nervous system (as is done in poisoning by narcotics) is the object of the Brand bath, and right well is this accomplished.

The lethargic patient arises from the bath refreshed, invigorated, with brightened eyes, just enough fatigued to drop into gentle and much needed slumber—a halt, brief and feeble though it may seem, is made in the steady but sure progress of the toxic undermining of the nervous system. The latter again lapses into lethargy, not always evidenced, as I would have you bear in mind, by delirium or stupor, but just as surely evidenced by the rapid and compressible pulse, the shallow and rapid respiration, pale or cyanotic hue of the countenance, deadly cutaneous pallor, diminution of urinary excretion of toxic elements, etc. Again the patient is submerged, again he is rubbed and douched, and again the enemy is thrown into confusion for a longer or shorter period. Thus step by step his advance is disputed. Oh, how weary and full of travail is the fight to patient, physician, and friends!

But day by day, with occasional disappointments, a fifth, or a quarter, or a half degree of temperature is gained; the heart maintains its vigor, the kidneys increase their work, the stomach receives more kindly the proffered nutriment, and sleep is won.

The enemy cannot be routed, the disease cannot be shortened, but we hold him in check surely and completely until his reinforcements fail. The bacterial life period reaches its end, the toxins cease to be evolved, and at last the physician stands conqueror of this deadly enemy. This is the true aim, the correct rationale of the Brand bath. Were temperature reduction the chief need, we would hold the key to the situation in our splendid coal-tar antipyretics; were pulse reduction the desideratum, *veratrum viride* would prove an "open sesame;" were nourishment the chief object, there is no lack of this in modern culinary and chemical art. But all these are as naught in the face of a toxemia which overwhelms the nerve centres of the most robust, as well as the most feeble, patients.

That the cold bath devised by Brand meets the issue has been shown by the most incontrovertible statistical data in medical history.

Why deviate from the method except for good reasons? To wrap the patient in a sheet and then sprinkle him with ice-water, as was done in the case cited above, is a deviation from the correct technique of the typhoid-fever bath. Such a procedure does not fulfil the main object of arousing the nervous system. After the first shock has passed no opportunity is given for reaction, because the sprinkling of ice-water continues; the cutaneous vessels and the elastic tissue of the true skin contract, as evidenced by cutis-anserina; the extreme cold imparted by the wet sheet, without remission, benumbs the sensory nerves and thus impedes the transmission of the shock and subsequent stimulus, even if the latter has ensued in an exceptionally strong individual. The absence of friction in this faulty technique (which in the Brand bath stimulates to reaction, and by widening the blood area of the skin cools a large quantity of blood) frustrates completely the true aim of the cold bath.

The surface temperature is indeed reduced by this improper method, but the blood is driven to the interior, congestions are favored, the organs are overloaded, and the patient emerges from such a bath (save the mark!) a shivering, cyanosed weakling.

Even such a sheet-bath as was used by the distinguished hospital attendant referred to could, by proper understanding of the rationale, be made to serve a useful purpose. If temperature reduction were not the object, but nerve stimulus; if the sprinkling were done rapidly with water not less than 60°; if each part sprinkled were thoroughly rubbed with the flat hand of an attendant until warm, and thus every part of the body sprinkled, rubbed, slapped and warmed up until it no longer responded by warming up, the dangerous contraction of the cutaneous vessels would be obviated, the vaso-dilators would be stimulated, a reaction would take place whose transmission to the brain would be salutary.

That the false procedure above quoted proved fatal is due to an error in technique based upon a misconception of the rationale of the cold bath in typhoid fever.

I am happy to state that both preceptor and pupil are now practicing the Brand method with success. They have mastered the technique and follow it closely with rare exceptions. That the best judgment must be applied to the technique of this treatment becomes apparent very soon to the observant practitioner. The ideal results obtained by

Brand and others in 1200 cases without mortality can only be realized by following the exact technique of Brand. This consists of beginning the friction baths at 65° before the fifth day, and continuing them without fail every three hours, night and day, when patient is awake, so long as his temperature reaches 102.5°. V. Ziemmsen testifies whenever he deviated from the strict Brand method he had cause to regret it, and my own observation corroborates his experience.

I have repeatedly pointed out that even eminent clinical teachers have failed to obtain ideal results because they deviated from the ideal technique, each one modifying it to suit his own fancy. That physicians must blindly follow the dictum of Brand or of any other is not demanded, but the Brand method, which is definite in its technique, must not be charged with failures attending its modification any more than Bergman's aseptic surgical technique should be charged with failures attending the neglect of any one of its exacting demands. For instance, the physician who does not begin bathing before the diagnosis is positively made by the roseola cannot expect that freedom from lethal complications which early bathing surely brings, though he bathe exactly according to Brand throughout the case. He will surely have a smaller mortality than another who begins regularly in the second or third week, or one who uses higher body temperatures as indications for the bath, or one who adopts higher bath temperatures to please the patient or his friends. I plead for attention to the *exact technique* of Brand in all cases not presenting distinct contraindications.

That a few such cases do occur my own observation has demonstrated. Hospital cases, for instance, rarely come in before the fifth day; hence the constant prevention of diarrhea, tympanites, hemorrhage and perforation is impossible. In private practice it is my custom to bathe so soon as the symptoms are at all suspicious. That benefit is derived from bathing in any febrile disease cannot be denied. While, therefore, it can do no possible harm, the early bath is an important step in the inauguration of the most successful treatment, if typhoid develops.

Professor Osler states, and his opinion may be confirmed by all who follow Brand's technique strictly, "that consciousness is restored, stupor is removed, the heart is invigorated, sleeplessness is diminished, and mortality is reduced to a minimum by these baths."

Such results can only be obtained by mi-

nute attention to all the details of the Brand method; the latter is an innovation upon all other cold-water treatment, be it by baths, douches, or affusions, which are to reduce temperatures.

I have dwelt so long upon this illustration of my subject because extensive observation and careful inquiry among practitioners in Germany and in this country have convinced me that to losing sight of the true principles of the Brand baths, and consequent too liberal deviation from its correct technique, may be ascribed the lack of appreciation of the therapeutic value of this method of bathing, and its consequent feeble recognition by the profession. Those physicians who have mastered its technique will agree with Professor Delafield, who said in a clinical lecture in December, 1892, at the Roosevelt Hospital, that "First, immersion in cold water is the only real treatment of typhoid fever; second, the only way to practice this treatment is the exact method of Brand."

The view of this justly eminent teacher is rendered more valuable for the purpose of illustrating my theme by the fact that on February 18, 1890 (nearly three years previously), Professor Delafield said in the New York Academy of Medicine, while discussing my paper on the treatment of typhoid fever, that "he had no real experience with the Brand method of cold bathing; that the point brought out in the paper that in the United States we have never really tried this treatment was correct. It was a fact, he believed, that scarcely any one here had carried out the whole treatment thoroughly" (*New York Medical Record*, March 22, 1890, p. 336).

Here is an illustration of true scientific candor. A great teacher becomes convinced of the value of the Brand method and of the necessity of an exact technique; he at once puts it into use in his practice, and in three years gives his students the result in that pithy manner for which he is noted. Can there be a more telling illustration of the value of exact technique in hydrotherapy than these candid statements of this eminent teacher?

Physicians always insist upon exact dosage of medicinal agents, the exact time and mode of their administration, frequency of repetition, and even their exact preparation. I plead here for the adoption of similar care and attention to the prescription of water as a remedy.

That precision in technique is quite as important in the treatment of chronic diseases

as in the acute may be readily demonstrated. That the medical profession has not yet accepted the idea is illustrated by the announcement of a certain hydrotherapeutic establishment which reads, "Give the bearer a douche, sulphur bath," etc.; the physician may strike out the bath "not wanted." One may as well write a prescription reading, "Give the patient a dose of quinine, morphine, or sulphonal," without specifying exact dose and mode of administration. Such a prescription would be regarded as incomplete, indeed as absurd. That a prescription for a bath or other hydriatic procedure without exact statement of temperature, duration, pressure and method is equally absurd, needs but to be pointed out.

The import of pressure, temperature and duration of every hydriatic procedure requires to be impressed with emphasis. Every physician realizes the difference of effect arising from different temperatures, and yet we commonly read directions for cold baths, tepid baths, hot baths. By a cold bath is commonly understood a bath to which no hot water has been added. Such a bath in New York City would be 45° F. in midwinter and 75° in midsummer, as ascertained by exact observations in the Hydriatic Institute. That 30° would produce an enormous difference in effect goes without saying. And yet the exact temperature of a bath is rarely designated.

Just as the Bränd bath has failed in the hands of those who modified or changed its technique, so has hydrotherapy in chronic cases failed because of inexact technique. I reiterate that temperature, pressure, duration and method should be prescribed and practiced with as much exactness as the dose, prescription and method of administration are stated in prescriptions of medicinal agents. The treatment of phthisis may serve as an illustration. There is no chronic disease whose intractable character is so well established, and yet I may say without fear of contradiction that it is more amenable to treatment by hygiene, correct diet and a judicious hydrotherapy than many other diseases which are regarded as more difficult to treat. Especially in the earlier stages, ere the temperature becomes elevated and the pulse becomes rapid, when the chief manifestation is a general depreciation of the nutrition, which in the progress of tuberculosis becomes the main reason for the advance of the latter, I have observed favorable results from hydrotherapy which are striking and instructive. In the wards of the Monte-

fiole Home for Incurables, where cases are observed by a large staff of expert medical men, and in my private practice, where microscopical examinations have been made of the sputum in the Vanderbilt Laboratory, and by other experts, these favorable results have again and again been verified. The proper technique in these cases was based upon improvement of the nutrition. That by a judicious application of douches, of moderate and low temperatures, such improvement may be obtained there is no doubt. The method evolved from practical observations which I have introduced at the Montefiore Home is a gradual but progressive accustoming of the patient to low temperature and high pressure. We begin with dilating the superficial cutaneous vessels and thoroughly warming the patient by a dry pack—*i.e.*, an envelopment in long-haired blankets or a hot-air bath, short of perspiration. Thus prepared the patient is subjected to a circular or needle bath under twenty-five pounds pressure at a temperature of 95°, gradually reduced in the course of one minute to 85°, and followed by a fan douche of 90°, reduced daily by one degree at a pressure of twenty pounds until 65° F. and thirty pounds pressure are reached. Thus the stimulating effect of a stream of water thrown upon the surface under pressure counteracts the possible heat-abstracting effect of a water temperature, which is comparatively low because the patient had perhaps never been exposed to it. The shock to the sensory nerves is gentle, the reaction proportionately so. These are intensified daily until a decided reflex effect is produced upon the respiration, deepening it, the circulation steadying it. The heart becomes more vigorous; more oxygen is inhaled if the patient be made to walk gently in the open air after the treatment. The result is an improved hematosiis, a better circulation in the stomach and other organs, a stirring up of the leucocytes—in brief, what is called a general tonic effect.

If this careful technique be not observed, if the patient be subjected to lower temperatures or higher pressures in the beginning, his reactive capacity would not be equal to the demand and the result would be serious and discouraging. To illustrate I may refer to a recent incident. A young hydrotherapist, recently returned from Germany, expressed great surprise that a case of phthisis which had been under hygienic treatment and diet, improving and gaining weight

steadily, had begun to lose weight after douches had been used one week. To her question as to the probable cause of this result I replied that there was "something wrong with the hydrotherapy used in the case." Upon asking her to detail the technique, she said that she had followed the plan adopted at the Montefiore Home—to dilate the cutaneous vessels before applying the douche. When she was asked how long the patient remained in the hot-air bath, the reply was "until she perspired freely." Here was the defect of the technique.

The object of the hot-air bath in phthisis and other diseases manifesting defective nutrition and a tendency to emaciation is to dilate the cutaneous vessels for the purpose of influencing reaction, but not to promote tissue change, as evidenced by excessive rise of temperature and perspiration. As the latter method is adopted in treating obesity, its inappropriateness in phthisis is at once apparent. Bearing in mind the feeble circulation in phthisical patients, a gradual education of their reactive power, a daily neuro-vascular discipline as it were, accomplishes results which are striking. I have published the records of cases in which weight was increased, cough, fever and bacilli disappeared, which have remained well and living in New York three years, though they had been condemned to exile by eminent consultants. I well remember a case in the Montefiore Home which gained thirty-three pounds. No specific effect—bactericidal, as is now the fashion, or otherwise—is claimed; the effect is solely and simply an improved nutrition and probably a more active circulation of leucocytes in the main vascular channels, which has been demonstrated by Winternitz and confirmed by Thayer and others.

In cases of neurasthenia, atonic and nervous dyspepsia, simple chlorosis, the results of hydrotherapy applied with judgment and skill in building up nutrition and improving hematosis are striking. As Dr. Draper has justly said in his valuable paper on Hydrotherapy, read before the Academy a few years ago, "its results in certain chronic diseases are striking; it seems to be more effectual than medicines."

There are many cases, indeed the large majority in the hands of the general practitioner, for whom institutional treatment is not available, and who demand immediate attention. To manage these successfully demands a closer study and more thorough acquirement of the rationale and technique

of hydrotherapy. Such enlargement of knowledge will redound to the benefit of patient and physician alike.

An example of faulty hydrotherapy may be of interest here. In a published lecture on neurasthenia, delivered by an eminent neurologist, the following may be found: "The cold-water treatment in the morning is apt to bring about a very beneficial change. I will suggest various methods of applying the treatment, which you can use in all cases, rich or poor, old or young. The top of the head and the nape of the neck are points of attack. Have the bath-tub one-third full of lukewarm water, so that the patient may stand in it without getting chilled; then, if the bath has a douche attached, you may allow the shower to play on the top of the head and then down the nape of the neck; or you can slap the nape of the neck and the spine with towels wrung out of very cold water; or let him take a large sponge dipped in cold water, put it on the top of his head and let the cold water run down his back. Nothing produces so good an effect on the nervous system as the trickling of cold water; it is not so good simply to wash with cold water; trickling out of a sponge is the proper way to apply cold water. No matter what the origin of the neurasthenia may be, it is best to begin with this cold-water treatment."

Note the indefiniteness of this technique. According to the locality in which *cold* water is administered its temperature may be 40° in midwinter or 80° in midsummer. And yet this lecturer says not a word about temperature. The trickling of cold water over the body needs but to be mentioned to provoke a feeling of chilliness; playing a douche of cold water over the head and spine of a neurasthenic of the excitable type would set him wild, while the same treatment may benefit the depressed neurasthenic if it be brief and daily and gradually lowered.

The recklessness of these suggested modes of applying cold water becomes more glaring when compared with the same lecturer's directions for the drug treatment. He says: "I often see cases where strychnia is needed badly. You may give any of the salts of strychnia. The proper way to administer the drug is in pill form or in mixture. Begin with  $\frac{1}{80}$  of a grain three times a day; if the patient tolerates strychnia the dose should be increased until he takes  $\frac{1}{30}$ , or  $\frac{1}{20}$ , or even  $\frac{1}{10}$  of a grain three times daily."

This lecturer is equally explicit with regard

to phosphorus, stating the preparation, dose, combinations, etc. If he had followed this course in describing the water treatment by stating the temperature of cold water and of the *very* cold water; the pressure of the douche, which from the height of a few feet is a chilling drizzle, while from a height of fifty or sixty feet it stings and arouses the vaso-motor nerves to an intense and pleasant activity; the duration of the treatment, which if left to the patient often bears unhappy consequences; he would not have left them ignorant of the proper method. I am glad to say that this teacher has recently published a valuable work on nervous diseases, in which the directions for hydrotherapy are quite precise and well considered.

Another eminent teacher advises neurasthenics to plunge into a tub of warm water (temperature not being stated), then allow cold water to run into the tub until the water surrounding the patient is cool; this temperature again being left to the judgment or caprice of the patient. Here the very common error is committed to obviate shock. This is the horrid bugaboo of inexperienced prescribers of cold water, who disregard the fact that the reaction following the shock is the aim of hydrotherapy when applied as a tonic or as a nerve stimulus, and that the reaction is exactly in proportion to the preceding shock. The bath just referred to does not fulfil its object properly, because the surface vessels are relaxed by the warm water; reactive capacity is diminished by its calming and sedative effect. The vaso-constrictors are depressed. The subsequent cooling of the water finds the sensory nerves unprepared and chilliness usually results, unless the patient be more robust than is the average neurasthenic.

It is unhappily a very prevalent error to regard the most agreeable bath as the most salutary. We do not so reason in the application of medicinal agents, of electricity, or of diet. And yet the application of water may be made agreeable by gradually accustoming the patient to lower temperatures, slowly reducing them every day or two, making the application brief at first and increasing the duration and pressure day by day. The prime essential, however, should always be borne in mind that *reaction is our aim*, that this cannot be evoked without some shock, that the more intense the latter the more effective the reaction; but the more brief it is, the less unpleasant. If the physician bear in mind that his object in treating such a

case is an increase of the quantity of blood circulating in the cutaneous vessels, an enhancement of the nutrition, a stimulus to the entire nervous system, he will endeavor to so order the technique, provided he has mastered its details, as to evoke this salutary reaction. A chlorotic girl, for example, should stand in a tub containing twelve inches of water at 100° to protect her against chilling of the feet. Water at 90° F. or lower, according to the assured reactive capacity of the patient, should be ready in a large basin or a small tub within reach. The mother or attendant squeezes a small crumpled up towel or two bath gloves out of this water and rubs the patient gently, occasionally pressing the water against the body, till the whole body is so treated. The rubbing should be done rapidly and chilling should be avoided. The patient is dried with a soft linen towel, which acts like blotting paper; then gentle friction is made with a Turkish towel. Where reactive capacity has been improved no friction should be made. Such a bath will prove refreshing and invigorating and prepare the patient for a more effective one without a severe shock. The temperature of the bath water should be reduced daily one or two degrees until 60° F. are reached; then larger quantities of water should be poured upon the body by squeezing a large sponge quickly over different parts. Later, pitchers or basins full may be poured over the body with some force; each change beginning with 90° and reducing daily one degree or more until 60° are reached. Thus day by day the reactive capacity may be elevated and tested, and no harm can ensue.

As the shock and reaction increase day by day, the patient will emerge from the treatment with a ruddy hue. The increased circulation will endure more and more every day, languor and loss of appetite will cease, and if the patient does not recover under this domestic treatment, douches of the same temperatures and with a pressure of twenty-five to thirty pounds, preceded or not by hot-air baths, will bring about a final restoration of health. "It goes without saying" that other hygienic agencies, the removal from unfavorable environment, properly regulated exercise and rest, enhance the value of hydrotherapy in all cases.

For the attainment of satisfactory and definite results, however, correct technique is paramount. This cannot be too often reiterated and impressed upon the profession. Acute cases like typhoid fever and pneumonia

are under constant observation of the physician, who may at once note the result of an improper hydriatic technique and modify it, or, as is more often the case, relinquish it altogether. In chronic cases much damage may be done before the physician discovers it, if the treatment be not in the hands of trained and intelligent attendants who are under medical supervision. Too often the details are left to laymen because physicians have not received instruction in the rationale and technique. The result is as Dr. Vogl, General stabsarzt of der Bavarian Army (*Münch. Med. Wochenschrift*, 27, 1896), says: "Physicians are themselves to blame if hydrotherapy is chiefly practiced by laymen, who know as little of the disease they are treating as they do of the effect of water, and thus damage not only the patients who confide in them, but also the cause of hydrotherapy."

During the past summer I visited in Germany and France twenty-five institutions in which hydrotherapy is practiced largely. I was astonished and chagrined to find among the number only four which had a stationary thermometer to indicate the temperature of douches, and only two which had gauges in use to indicate the pressure applied. How can these gentlemen control the technique with any degree of certainty?

It occurred to me that a mild and graduated hydrotherapy, such as is described above as in use in the Montefiore Home, would be capable of early adoption, and thus afford the patient great aid in improving his condition without the lapse of precious time.

To avoid shock and gradually educate the patient's reactive capacity has been demonstrated as a good rule of practice in my clinical observation. To enable me to accomplish this end with precision I have, without neglecting other hydriatic procedures, resorted chiefly to douches, with which I am able to grade the temperature, duration, and pressure.

For this purpose I have constructed an apparatus which has been used for several years in the Montefiore Home and the Hydriatic Institute in this city, in the German Hospital of Philadelphia, and in several other institutions. By this means it is in our power to exactly adapt the necessary shock and reaction to the patient's capacity and endurance.

Gentlemen: I hope to have clearly demonstrated:

1. That the therapeutic application of water demands at least as much care as the use of medicinal agents.

2. That owing to the flexibility of water as a remedial agent, greater demands are made upon the practitioner than in the use of medicines.

3. That the best results may be obtained only by following an exact technique in each case.

4. That the reason that different results are obtained by different physicians from the application of water may be found in the technical errors committed on account of an erroneous conception of the rationale of hydrotherapy.

I hope to have this evening aroused sufficient interest in hydrotherapy to induce you to acquaint yourself more intimately with its technique.

In the discussion which followed this paper Dr. I. Adler said that in the most modern medical view hydrotherapy plays an important rôle, and that, as Dr. Baruch had emphasized, the application of water is so lax that clinically and diagnostically much less is accomplished than would be otherwise. But this is not alone the fault of physicians, but perhaps as much of those who specially cultivate hydrotherapy. The latter seems to be based more on personal impressions than scientific data. We cannot accept water therefore on the same basis as our medicinal agents. As an example, the physiological action of strychnine upon the spinal cord is exactly known, but of water we cannot say this. There should be a knowledge of the physiological action of water ere we are asked to accept it as a scientific remedy.

Dr. Adler thought it was going too far to accept the baths as the only remedy for typhoid. The statistics cited by Dr. Baruch to prove that the mortality has been reduced to almost nothing are new to him. Dr. Adler has used the bath more in hospital than in private practice, where it is more difficult to apply. One may have very good results without baths, although the latter are one of the very best agents where the heart is feeble, delirium is intense, and somnolence occurs. But he could not accept Brand's rule, supported by Dr. Baruch, that 102° F. should be the signal for baths. Some patients become delirious at 100.5°; others may have 105° and not be delirious. Dr. Adler also confessed his confidence in small doses of antipyretics, which afford much relief, although he does not approve of their routine application for temperature reduction.

Dr. L. Weber said that he always used cold baths in typhoid in the absence of kidney

complications; he begins the treatment with a large dose of calomel to clean the intestinal tract and disinfect it. In private practice he has not often had an opportunity of applying the Brand method. There seems to be a silent but active opposition to it among the nurses. There is no doubt that Brand's method offers great advantages, and is specially adapted for enhancing the resisting capacity of the nervous system. Dr. Weber uses antipyretics in small doses for temperature reduction.

In neurasthenia Dr. Weber has seen much of hydrotherapy. It seemed to him, however, that many of these cases recover under any treatment.

Dr. A. Rose opposed Dr. Adler's views that hydrotherapy was not based upon sufficient scientific investigations and experiments. It would seem that the statements of quacks are more regarded than these scientific experiments. He referred to the pletysmograph of Winternitz, by which the passage of blood driven from one part of the body by cold baths was demonstrated in other parts. Dr. Rose referred to his experience in erysipelas and his observations with the permanent baths in obstinate rheumatism.

Dr. A. Seibert believed that the complaints made by hydrotherapists that their doctrines have not been generally accepted by the medical profession are to be charged to their own writings, in which they use many hyperboles. The Brand bath is not responsible for the reduction of mortality of typhoid fever during the past thirty years, but rather to the general improvement in the treatment of the disease. A large acquaintance with statistics enables him to say that many sins are committed by statistics. In his hospital practice Dr. Seibert uses the Brand method only on patients who are received in a somnolent condition. He prefers to reach the seat of the disease by cleaning and bathing the intestinal tract rather than to cool the skin and thus excite the nervous system.

Dr. Seibert regards as novel the claim that the early adoption of the Brand method is capable of affording absolute protection against complications. He refused bathing in pneumonia cases, and stated that an experience of nineteen years warrants him in proposing the doctrine that the patient's chances in pneumonia are better the less he sees of the physicians.

Dr. Talmey believes that one reason for the non-acceptance of hydrotherapy lies in the objections of the public; another reason

lies in the insistence of the hydrotherapists upon so many details, which no ordinary man is supposed to be capable of executing as well as they.

Dr. Baruch closed the discussion by regretting the brief time at his disposal. He insisted that much proof exists showing that the action of water is more rational and scientific than that of any other remedy. Very little is known of the action of strychnine in non-toxic doses. It may be administered for days, weeks and months without any subjective or objective evidence of its presence in the pulse, blood-pressure, respiration, etc. Our knowledge of its effects in disease is almost entirely derived from non-toxic doses. Of water we know much more. It may be dosed with precision afforded by a latitude of seventy degrees of temperature ( $35^{\circ}$  to  $110^{\circ}$ ), a duration of a second to many minutes, a pressure of from one to forty pounds. We also have various methods of applying it—packs, baths, douches, etc.—by which its effects may be graded. A few days ago he subjected an attendant in the Hydriatric Institute to a tub-bath of  $80^{\circ}$  F. for ten minutes. The effect was at once pronounced upon the pulse as ascertained by the finger and the sphygmograph; the blood count showed an increase of 700,000 red cells and 1500 white cells in blood drawn from the lobe of the left ear. Is any analogous experiment with non-toxic doses of strychnine on record? So far from there being a lack of scientific experiments of the action of water, these abound within the past five years, having been made in Zuntz's and other laboratories by Breitenstein, Loewy, Knoepfelmacher, and others. Thayer, of Johns Hopkins Hospital, has confirmed the statements of Winternitz and Rovighi that the red and white blood-cells increase after cold water applications; the sphygmomanometer has demonstrated that the force of the heart is increased by them; Vinaj has shown with the ergograph of Mosso with exactness how the muscular power is enhanced by them. Roque and Weil have shown that the urotoxic coefficient of the urine in typhoid fever is increased many fold after the use of the cold bath.

That early cold baths prevent complications has been demonstrated as has no fact in medicine before. Dr. A. Vogl, Medical Director of the Bavarian Army, has collected from the records of the Military Hospital of Munich all the cases of typhoid fever which were treated during a period of forty years in this hospital. He gives the type of the

disease each year, the symptoms, the treatment, mortality, and results of autopsy. Since the strict bath treatment was adopted he found the mortality reduced to 2.7 per cent., while under other methods of treatment it had ranged from fifteen to thirty per cent. This proves that the result is not due to a change of type in the disease which the records show to have varied from year to year during this long period, but that it is entirely the result of the bath treatment which prevented lethal complications. Although the Brand method must be applied before the fifth day, every fever patient may be bathed with advantage. Dr. Baruch stated that he invariably uses it in private practice, that he declines to treat the patient otherwise, and that he has been dismissed from a case but once for this reason.

The most superficial study would demonstrate that water produces a thermic and mechanical excitation of the cutaneous nerve-endings which operates upon motor and sensory tracts as a reflex upon the circulation, respiration, and secretions. These demonstrations are so abundant in literature that Dr. Baruch regarded it as an act of supererogation to reiterate them here.

That a woman may be aroused from syncope by the simple sprinkling of cold water upon the face is known to almost every lay person, and the scientific explanation of this process is recognized by every tyro in medicine to be a powerful irritation by cold, which is conveyed from the cutaneous nerves to the central nervous system and thence by reflex to the vagus. This seems perhaps too simple; rabbits and guinea-pigs are not required for the "scientific" explanation of this powerful effect. If such sacrifices are demanded, however, to establish water as a scientific remedy, the classical experiment of Maximilian Schüller upon trephined rabbits may be offered. Schüller exposed the vessels of the pia, and placing the rabbits in water at different temperatures observed the effects of these applications on the animals; he demonstrated more clearly than has ever been done in the study of any medicinal agent the effect of these water applications. He showed conclusively that the latter called into action a hydrostatic effect which makes water a powerful agent for influencing the circulation of blood in an animal. Besides, Winternitz and others have demonstrated in the most exact manner by laboratory experiments that the corpuscular elements of the blood are subjected to such decided changes by water

applications that no medicinal agent is capable of approaching these effects.

A very fruitful but sadly neglected field lies here before the practical physician who does not meet hydrotherapy with a shrug of his shoulders.

To Dr. Talmey's insinuation that hydrotherapeutists are so insistent upon minutiae that "it is difficult for an ordinary mortal to follow their directions," he would reply that modern hydrotherapeutists are constantly laboring to make hydrotherapy the common property of physicians. He would only protest against the tendency of physicians to leave the water treatment of chronic cases to bath attendants, or other nurses who claim to know all about it, but really do not know anything but the mechanical part. Does not every physician who orders a cold bath in typhoid fever give the nurse directions regarding temperature, friction, drying, duration, etc.? Why then should physicians leave such important details to a nurse when ordering a wet pack, douche, etc., for a chronic case? Would it not be far easier for physicians to consult some work on this subject and use their own judgment in ordering the necessary temperature, duration, etc.? It is just as absurd to leave these important details to self-important bath nurses as it is to leave the doses, etc., of a medicine to the druggist to prescribe and administer. Indeed the latter would be safer, because the druggist is at least an educated man. As Vogl has said, leaving the treatment in the hands of lay people has brought hydrotherapy into disrepute. He warns the profession against this error.

With regard to clinical observations this discussion again makes evident the fact that many physicians have occupied themselves with hydrotherapy insufficiently. In reply to Dr. Seibert's statement that the Brand method is not entitled to the credit of reducing the mortality of typhoid fever, Dr. Baruch referred to Dr. Vogl's statistics for positive evidence to the contrary. Moreover Prof. C. Gerhardt, of Berlin, said in his recent opening lecture before his class at the University: "The mortality of typhoid fever has been reduced by the Brand cold-water treatment to one-fourth."

That Osler formerly regarded heart feebleness as a contraindication to cold bathing does not disprove the fact that he is now its warm defender, since he applies its technique correctly. In the first edition of his book on Practice he omitted the frictions from the

bath technique; this error has been corrected in the later editions.

That the hydrotherapists "resort to many hyperboles in their writings and lectures" may, as Dr. Seibert states, be true. But the most eminent physicians also resort to "hyperboles" when they have mastered hydrotherapy and applied it correctly. This he proceeded to demonstrate.

Prof. F. A. Hoffman, of Leipsic ("Lectures on General Therapeutics," 1892), says: "Herein lies the unexcelled value of cold water in therapeutics; we invigorate the nervous system and thereby enhance the cardiac capacity" (page 88). "I am convinced that in time all chronic organic diseases will come into the domain of the bath treatment" (page 392). "Cold affusions have justly been elevated to become the chief remedy in catarrhal pneumonias of children" (page 130).

Prof. Wilhelm Erb, of Heidelberg, writes in Ziemssen's Cyclopaedia: "Among the most effective and powerful agents in our branch are cold and cool baths and cold-water treatment. Its results in all possible chronic nerve troubles are extraordinarily favorable. We have few remedies which exert a similar powerful influence upon the nervous system."

Professor Kussmaul, of Strasburg, writes: "There is no doubt that the belief in the prescription is waning among educated people, and the confidence in dietetic remedies and the remedial value of water is in the ascendant. Water especially has won for itself a constantly growing confidence as a remedy, because unlike any other it may be applied by reason of varied temperature and methods to the most varied curative purposes."

Semmola, the recently deceased professor of therapeutics at the Naples University, whose work has been translated into German and supplied with a laudatory preface by Nothnagel, writes: "Hydrotherapy excites cutaneous activity and with it all functions affecting tissue change and organic purification, so that frequently real marvels of restoration in severe and desperate cases have been obtained by it."

From Prof. V. Leyden's Berlin Clinic, Klemperer reports (Publications of the Hufeland Society, 1896) that "in hydrotherapeutic effects we observe a quite extraordinary and incomparable stimulation of the nervous system which is exerted upon the various organs. . . . In our clinic we regard hydrotherapy as quite an essential factor in bronchial asthma. . . . Much greater is its rôle in nervous diseases of the heart—but

it plays quite a powerful rôle also in organic heart diseases. . . . As much more effective do I regard these hydrotherapeutic influences in stomach and intestinal diseases. Here hydrotherapy remains the most powerful factor. . . . I may say briefly that we have treated the most varied pathological conditions of the gastro-intestinal tract—chronic constipation, diarrhea, enteralgia—hydrotherapeutically with great benefit."

Dr. Baruch said that he might quote many "hyperboles" from the writings and lectures of the most eminent clinical teachers. These gentlemen have not been deterred by the "hyperboles of the hydrotherapists;" they have investigated the subject, as have Delafield, Peabody, Osler and Draper in our own country, and have become its advocates.

One thing Dr. Baruch desired especially to emphasize, namely, that in his article, as in all his writings, he has never lauded water as a universal remedy. Dr. Baruch claimed that his observations in hydrotherapy were gathered in the capacity of family and hospital physician, in which respect he stands alone. As a practitioner of thirty-five years Dr. Baruch did not feel prepared to throw aside calomel, salicylic acid, morphine, quinine, and other approved remedies. Despite this fact he felt compelled to acknowledge that water had served him well in the most desperate chronic cases after other most approved remedies had failed in his own hands as well as in the hands of colleagues. For this reason he would say with Pindar, *αριον μὲν ὕδωρ*. And herein he felt himself sustained by the most eminent clinicians of the present time, whose opinions he desired to impress upon his colleagues.

---

#### SOME CASES OF MASTOIDITIS, WITH REMARKS.

---

BY GEORGE B. MCAULIFFE, M.D.,  
Assistant Surgeon of the New York Eye and Ear Infirmary.

---

The following cases of mastoiditis occurred almost in succession, and exemplify the polymorphous character of mastoid inflammation and the difficulty of avoiding the lateral sinus which, though not such a bugbear, nevertheless makes the aurist careful in the use of the chisel. No one desires to strike into the sinus involuntarily, although such an error would be condoned by any one who has done a sufficient number of "mastoids" and has learned at last that he does not know the position of the lateral sinus, except vaguely.

Dr. Myles, who has made many mastoid openings on the cadaver, points out the fact that the approach to the sinus is shown by the increasing density of the bone and the bluish color. In life this does not apply. Very often one is in doubt as to whether he has uncovered the sinus or a mastoid cell, and uses the curette gingerly until he is certain. The sinus appears like a bluish-white bubble, which is more resilient and harder to the probe than a cell. Even when working near or in the triangle which embraces the antrum (I refer to that made by tangent lines to the upper and posterior walls of the canal) one sometimes exposes the sinus, as is shown in one of the following cases where the bone between canal and sinus was a prismoid in shape. The sinus was uncovered first and the antrum was found subsequently beneath the sinus in the depths of the prismoidal bone. Then, again, the mastoid will be laid bare and the bone chiseled away for a considerable distance posteriorly, without encountering the sinus. This seems to be more so on the left side.

These cases further show that it is sometimes a difficult matter to tell when to operate. A few days' treatment with the ice-coil will sometimes disguise and dull the symptoms of mastoiditis. When finally operation is decided on, the bone will be found in such a condition that one must conclude that the operation should have been done earlier. Again cases seem most urgent, yet when opened the mastoid shows no pus. Bad cases sometimes show constitutional symptoms, sometimes not. A woman had grippal earache, profuse otorrhea, mastoid tenderness with some little edema, and slight temperature. The coil took away most of the tenderness, but the edema and low temperature still remained. The canal did not bulge to any extent.

Operation showed a perforation in the tip. The mastoid was a shell and the sinus was easily uncovered for an inch. There was little if any mastoid left, and yet she laughingly objected to the operation five minutes before.

The most constant symptoms, in cases demanding operation, are a temperature, a profuse or thick discharge which the ice-coil does not stop, a sagging canal posteriorly near the drum, tenderness which may not always be pronounced, although it exists in almost every case and is generally elicited on deep pressure over the site of the antrum or tip.

In children it is sometimes very hard to decide when to operate. Tenderness is not always manifested by the little patient. The discharge may be stopped. Inspection of both ears from behind may show the diseased one more prominent than the healthy. The baby whose case is given below evidenced very few signs of trouble except a slight prominence of the ear and the thick discharge. It was cheerful and nursed well up to the day of the operation. Then it could not be induced to smile, was quiet and listless, and for the first time refused to take much nourishment. In children as a rule it is not wise to wait too long. The bones are so soft that they break down more easily and the pus finds accommodation in many more directions than in adults. In regard to preliminary treatment of the otorrhea, two of the cases were treated from the incipency with antiseptic tamponage, which was generally renewed once daily. The discharge was profuse and thick, and the gauze did not drain well. The mastoiditis developed promptly enough, and the cases seemed to be harmed more than benefited by the tampons. While this treatment acts admirably in many cases it has its limitations.

Great care must be exercised in watching the case. Each case is a law for itself, and no one can tell how long it is necessary to leave the dressing undisturbed. If left too long it proves to be irritating and blocks drainage. In cases such as those mentioned it is far better to rely on frequent antiseptic douches, with light dressing of gauze. Where the operation is thorough the after-treatment is generally uneventful. Cases sometimes develop a high traumatic fever which makes one a little uneasy, but the ultimate results are very good. The wounds do well without much douching after the operation unless pus be present.

CASE I.—Schoolgirl, seventeen years old, had a cold in the head since Christmas, 1896. On January 19 had nocturnal earache, which lasted for the next two days. She came to the Eye and Ear Infirmary, and after bichloride douche I did a paracentesis on the bulging left drum. The discharge was seropus. Gauze drain was introduced, and patient did not return for two days. She stated that the earache had not abated. On the day previous she had had a chill. The discharge had become profuse, and the gauze was thoroughly saturated. She had mastoiditis well developed. Her temperature was 101.4°. The ice-coil was applied, and pa-

tient put to bed. On January 23 pain had diminished. The canal was bulging slightly. Operation was done on the 25th. Mastoid was opened and carious bone removed for a considerable extent posteriorly; an unusual number of cells were found and scraped. This accounted for the tenderness extending far back. The wound was a very large one. Her temperature on the 26th was 102° and fluctuated around that until the 29th, when it dropped to 99°. She was in bed eleven days. Her temperature, associated with some tenderness along the sterno-mastoid muscle, occasioned some uneasiness, but her general condition was good. In two weeks she left the hospital. On March 17 the wound was almost healed. Hearing distances with the watch were on the left side four feet and on the right six feet.

The principal points in this case are the high traumatic fever after the operation, the extent of bone operated without encountering sinus (thus seeming to prove the statement that the sinus goes deeper into the bone on the right than on the left side), and the dangerous part played by the gauze left in too long.

CASE II.—Julius Leboist, five months old. The child was treated in the clinic for two weeks by means of antiseptic tamponage renewed daily. The discharge did not stop. Paracentesis was done at the end of the first week to promote drainage. The pus was more profuse after the cutting. On account of the apparently defective drainage, and the slight, almost inappreciable, prominence of the pinna, the child was taken into the hospital and the coil applied on February 4. The temperature was 99°. The discharge did not stop under the use of the coil; it was thick and tenacious, and the canal was stenosed. The mastoid showed no more edema or redness, and the temperature ranged between 99° and 100°. It was hard to decide as to whether the child needed a mastoid opening or not. The infant nursed well, smiled, and continued on so until the 10th, when it was noticed that he was quiet all day and would take no nourishment. The local symptoms remained the same, with slight edema above the pinna. The operation was then performed. The sinus was exposed for three-quarters of an inch. The necrosis extended to the squamous portion, of which a piece the size of a quarter of a dollar was removed. The dura was found rough in a small area. On February 23 the baby was discharged. The recovery was uneventful, his temperature only once being as high as 101°.

CASE III.—Patient had otorrhea for two years. A week previous to entering hospital he had earache. He used home remedies and packed the ear with cotton. Mastoiditis developed. On February 23 he was admitted and the coil put on. His temperature was 101° F.; this soon dropped to 99°. On the 26th the tenderness still existed, with very slight bulging of the posterior wall, but no edema. The mastoid was opened and the sinus was found close to the canal separated by a ridge of bone. The sinus was explored with negative result. No antrum was discovered. On the 28th of February the ridge of bone separating the canal from the sinus was chiseled away, and the antrum was found beneath the sinus in a prismoidal mass of bone. His after history was uneventful. His temperature ranged between 98° and 99°. March 20 he was entirely well.

---

#### COUGH AND ITS TREATMENT.\*

BY THOMAS J. MAYS, A.M., M.D.,  
Professor of Diseases of the Chest in the Philadelphia Polyclinic, and Visiting Physician to Rush Hospital for Consumption in Philadelphia.

Cough is a reflex movement. It depends on irritation of the sensory fibres of the pneumogastric nerves, the impulse from which, being transmitted to the ganglia or to the root of the latter, is referred back to the lungs through the motor filaments of the same nerve, and there manifests itself in the complex phenomena of expulsive contraction which we know as cough. In order to comprehend the varied and manifold conditions under which cough may arise it is important to briefly study the origin, course and distribution of this nerve. It may be described as arising from two nuclei, one of which is situated in the lower half of the floor of the fourth ventricle, and the other in the oblongata near the olivary body. In the jugular foramen, through which it emerges from the skull, is the ganglion of the root of the pneumogastric, which in all probability is the homologue of the ganglion on the posterior root of the spinal nerves (see figure below). From this ganglion is given off the *auricular* branch which supplies the external ear and the *membrana tympani*. Only a short distance below this point is another enlargement, about an inch long, which is known as the ganglion of the trunk. Here the pneumo-

---

\* Lecture delivered at the Philadelphia Polyclinic.

gastric anastomoses freely with the spinal accessory and receives filaments from the sympathetic and the hypoglossal, and from the upper part of this ganglion the *pharyngeal nerves* are given off. The *superior laryngeal nerve*, which supplies sensation to the mucous membrane of the *larynx*, *epiglottis*, and base of the tongue, also arises from this ganglion. The next branch which is given off is the *recurrent*, or *inferior laryngeal*, which is the motor nerve of all the intrinsic muscles of the larynx except the cricothyroid, which receives its innervation from the superior laryngeal nerve. Before the pneumogastrics enter the

Diagram of pneumogastric nerve and its branches.

lungs they form the *anterior* and *posterior pulmonary plexuses* in connection with the sympathetic, and from thence their fibers run along the *bronchial tubes*, the pulmonary arteries, and throughout the lung tissue. On the outer surface of the bronchial tubes, as well as in the textures of the lung, are found a large number of small ganglia in connection with these nerve fibers, and in many instances the nerve filaments of these seem to terminate in the *mucous membrane of the bronchi*. The nerves of the *pleural coverings* are also derived from the pulmonary plexuses, and those fibers which are distributed to the pulmonary pleura also have ganglia attached to them. Additionally branches of the pneumogastric nerves are distributed to the *heart*, *stomach*, *liver*, *intestines*, *spleen*, *kidneys*, and *suprarenal capsules*. From this it follows that irritation coming from the ear, larynx, trachea, bronchi,

lungs, pleura, heart, pharynx, stomach, liver, intestines, or from any part of its trunk or origin, is liable to produce and excite cough.

Not all these regions are equally sensitive in this respect. Thus Kierner, Koths and others have shown that in the respiratory tract the larynx possesses the greatest impressibility, while the trachea and bronchial bifurcation are less sensitive, the bronchial walls still less so, while the alveoli have very little sensibility. The pulmonary pleural lining is especially sensitive and very liable to cause cough.

I will now consider the different kinds of cough:

**Ear Cough.**—This cough is excited by an irritation of the auricular branch of the pneumogastric nerve. Arnold cites the case of a girl who had persistent cough and excessive expectoration, with extreme emaciation. It appeared that she had many months previously introduced a bean into the meatus of each ear, where they were discovered on examination. After the removal of these foreign bodies the cough ceased and the patient recovered her health. Accretion of cerumen in the ear is an occasional cause of cough, which will abate when the offending material is cleaned out. Aurists also know that the introduction of a speculum into the ear, or of a sound or probe into its cavity, frequently causes cough. A draught of cold air striking the meatus or the drum of the ear is followed by coughs and colds in some people independent of any catarrhal affection of the middle ear. This has led to the custom of plugging the meatus with cotton or wool, which shields and protects the oversensitive ear-surface of these people.

**Laryngeal Cough.**—Laryngeal cough depends on a supersensitive or inflamed larynx, and is accompanied by hoarseness, pricking or burning, and by a constant desire to clear the throat. The cough is dry and brassy, with very little expectoration, while on the other hand it may be moist with an abundant secretion. Its causes are principally a strain of the voice, especially in the open air; bad management of breathing in public speaking; the excessive use of alcohol and tobacco; the inhalation of dry hot air, dust, gases, etc. In the treatment of this form of cough the exciting cause must be removed. The inhalation of watery vapor impregnated with the compound tincture of benzoin, or the inhalation of the fumes of gum camphor, or of four or five drops of chloroform from a handkerchief, or the spraying of the larynx with a solution

of cocaine hydrochlorate, thirty to forty grains to an ounce of water, are very useful methods for allaying the irritability of the larynx. Lozenges containing cocaine hydrochlorate, sugar, licorice powder and powdered acacia, and allowed to dissolve slowly in the mouth, also have a soothing effect. At the same time the general health must not be overlooked. Strychnine, quinine, iron, the hypophosphites and cod-liver oil are exceedingly beneficial in this respect.

**Bronchial Cough.**—This is the cough which comes from catarrh of the bronchial mucous membrane, and one of its immediate offending causes is a collection of catarrhal material on the surface of the bronchi. The explosive movement of the chest muscles which we know as cough seeks to remove this impediment. Most patients who suffer from this kind of cough locate its source in the upper sternal region directly over the seat of the large bifurcation. This is probably due to the fact that so long as the bronchial epithelium is intact, the movement of its cilia tends to transport all the catarrhal material from the smaller into the larger tubes and thus to finally deposit it in the region to which the feelings of the patients refer it. Many a patient of this sort, not understanding the mechanism of his trouble, frequently expresses his belief that if he only could get rid of the worry under his breast bone he would be entirely well. Cough of this kind is always accompanied by a copious yellow expectoration which is generally most abundant in the morning on account of an accumulation of the latter during the previous night. There is, however, another bronchitis which is not associated with either a copious or a yellow expectoration, but with one that is tough, tenacious, grayish, and sparse. This is the bronchitis which has no direct connection with catarrh of the bronchial tubes, but depends on stasis or on hyperemia of the lungs due to cardiac disease, generally of a mitral nature, and is very liable to be accompanied by blood-spitting, a feature which is rarely present in the idiopathic form of bronchitis.

A distinction between these two types of bronchitis is of great practical value when we come to treat this disease. If the case belongs to the former type, and is not acute, then our chief aim is to build up the constitution, and secondarily the lungs; for that which enhances the general health will also improve the local condition. Among the agents which accomplish this purpose strychnine—and strychnine in large and progressive

doses—stands first. Begin with one-thirtieth of a grain four times a day in the adult and gradually increase the dose until you reach the line of toleration in the action of the drug. In most cases this does not show itself until one-sixteenth or one-twelfth of a grain is given four times daily, and sometimes as much as one-fifth or one-fourth of a grain may be given four times a day without any untoward results. If the toxic action of the drug begins to manifest itself then a smaller dose must be resorted to, which is to be again gradually increased until the line of toleration is once again reached. Then the dose is again reduced and again increased. The addition of the syrup of the hypophosphites is useful; so is cod-liver oil if it is well borne by the patient. For a simple cough mixture give the following combination:

- R Tincture benzoin compound, f ʒss;  
Fluid extract euphorbia pilulifera, f ʒss;  
Tincture capsicum, f ʒ iij;  
Syrup senega, f ʒ j;  
Syrup hydriodic acid, q. s. f ʒ iv.

M. Sig.: One teaspoonful in water every three or four hours.

A nutritious dietary is of course also essential. There is frequently present a strong gouty or rheumatic element in some cases of bronchitis. This must always be inquired into, and if this is done evidence of it will be found lurking in some parts of the body when from outside appearances it is wholly unsuspected. If this is present then the salicylates will do efficient work. It is my custom to give the sodium salicylate in the following combination:

- R Sodium salicylate, ʒ ij;  
Potassium acetate, ʒ j;  
Potassium carbonate, ʒ ss;  
Wine colchicum root, f ʒ iiss;  
Gaultheria water, q. s. f ʒ iv.

M. Sig.: One teaspoonful four times a day.

In bronchitis depending on a cardiac lesion the medication must of course be addressed primarily to the heart. Good results in such cases are obtained from the following:

- R Strychnine sulphate, gr. j;  
Quinine sulphate,  
Acetanilid,  
Caffeine citrate, of each gr. xxxx;  
Iron sulphate, gr. xv;  
Powdered digitalis, gr. x;  
Arsenious acid, gr. ʒ.

M. Make capsules No. xxxii. Take one capsule four times a day.

If there is present any rheumatic element in such cases add forty grains of sodium salicylate to the above prescription; or give the

above mentioned salicylate mixture in conjunction.

*Pleuritic Cough.*—Pleurisy, as is well known, gives rise to a persistent cough with little or no expectoration; and pleurisy being oftener due to rheumatism than not, it follows that the remedies which do good in the latter also prove efficient in the former affection; hence the salicylate of soda mixture recommended above in rheumatic or gouty bronchitis will also be found serviceable here.

*Asthmatic Cough.*—The cough of asthma is always accompanied by an abundant expectoration after the attack of asthma has ceased. During the attack the cough is dry, short, and hacking, and the patient suffering greatly for the want of breath. To shorten the asthmatic grip break a bead of amyl nitrite in a handkerchief and allow the patient to inhale it, or give two drops of a one-per-cent. solution of nitroglycerin in a teaspoonful of water, or administer hypodermically one-twentieth of a grain each of strychnine and morphine. One-twentieth of a grain of strychnine in a teaspoonful each of syrup of hypophosphites and hydriodic acid, four times a day, the strychnine being gradually increased, gives very good results. Asthma is very frequently mixed up with rheumatism, and hence the salicylates and the lithates are useful in its treatment. Lithia tablets, such as are now manufactured by many druggists, dissolved in a glassful of water and taken three or four times a day are frequently helpful. When the attacks are prolonged or run into each other they become very depressing and exhausting, and then the patient must be placed in bed and kept there until the fury of the affection is abated and until the former strength is recovered.

*Phthisical Cough.*—The cough of phthisis varies with the stage of the disease. In its incipiency the cough may be very slight, and indeed be absent in some cases; but in others it is one of the earliest and most constant symptoms, although there may be very little or no expectoration. In the advanced stage of the disease cough is more or less persistent, and so long as the catarrhal element predominates it is accompanied by an abundant yellow expectoration. After the formation of cavities the expectoration is generally of a grayish color and of tough, fibrous consistency.

We have already seen that cough is a reflex nervous movement, and hence it necessarily follows from a fundamental physiological law that the degree and amount of cough in any

case correspond with the irritability or incompressibility of the nerve-supply of the lungs. This applies more forcibly, perhaps, to the cough of phthisis than to that of any other form of lung disease, and explains why the cough of this affection not only varies very much in different individuals, but why it varies in the same individual under different bodily positions. In the very nervous phthisical individual the cough may be one of the most prominent and distressing symptoms from the beginning to the termination of the disease, while in the insane for instance, in whom the sensibility of the nervous system is in a great measure subdued and obtunded, phthisis goes through its various stages without any cough, and often very little expectoration. Then again, as a rule, the cough is easier when such patients sit or stand than when they lie down. This is probably due to the fact that the lying position allows more blood to gravitate to the apices, which are oftenest involved, and the increased fullness of blood thus induces greater irritability in the nerve filaments of these parts. It is also well known that patients can lie much easier on the healthy side of the body than they can on the side which is affected. This is perhaps also explainable on the score of the principle just referred to. Sleep is an obtunder of nervous irritability, hence the cough of phthisical patients, after they have once fallen asleep, is comparatively quiet during the night, but is always worse in the morning on account of an accumulation of material in the bronchial tubes during the sleeping hours.

It is clear, therefore, that the cough of phthisis is largely a question of nerve irritability, and that this element must be kept prominently before our minds in the treatment of this symptom. What then are the remedies for its abatement and relief? I believe that strychnine in progressively large doses is one of the best of these; it brings the tone of the nervous system within the range of health better than anything else. If the state of the nervous system is too irritable or unstable, it increases its stability and acts as a sedative; and if this is depressed below the normal level, it increases its tonicity and restores its elasticity.

Cayenne pepper ranks very high as a diffusible stimulant in the cough of phthisis. When phthisis follows the excessive use of alcohol it is of especial value, but under these circumstances it must be given in very large doses diluted with water. In ordinary cases

of cough the dose of the tincture may vary from two to fifteen drops four times a day, while in that of alcoholic phthisis I have seen doses from half to a teaspoonful, given at the same intervals, do a great deal of good. The powder may be used in doses of from one-eighth to one grain four times a day.

The liquid extract of *euphorbia pilulifera* and the compound tincture of benzoin in ten-drop doses with a drop or two of chloroform may be given in combination with the tincture of capsicum. Codeine at bedtime in doses of from a quarter to half a grain is sometimes required. Inhalation of a few drops of chloroform from a handkerchief, or of the fumes of gum camphor confined under a glass funnel, tend to quiet cough. The administration of a suppository at bedtime, consisting of from seven to ten grains of powdered asafetida, is very quieting. Morphine should not as a rule be resorted to until the last stage of the disease.

In cavities, bronchiectasis, or bronchorrhea, carbolic acid or creosote may be inhaled through a respirator with benefit. The cough which persists in the morning until the cavity is cleared out may be very much facilitated by teaching the patient to bend his head as low as possible, just as if he were in the act of tying his shoes, or going on his hands and knees with the head lower than the buttocks. These positions give the law of gravity a chance in expelling the offensive cavity contents.

Cough may be excited by congestion or inflammation of the pharyngeal mucous membrane, and by elongation of the uvula to such a degree that it touches the base of the tongue. Astringent gargles of tannic acid, sugar of lead, or the spraying of the pharynx with Dobell's solution, or with a weak solution of cocaine, or excision of the uvula, are the local measures which must be resorted to in such cases. At the same time it is also important to look after the general health of the patient. On the other hand cough may come from dyspepsia, from intestinal indigestion, from constipation, from disease of the liver, from gall-stones, from worms in children, etc. In such cases attention must be directed to the organ whose functions are disordered.

*Cough from Aneurism.*—There exists in nearly all cases of aneurism of the aortic arch a cough which is dependent on pressure of the aneurismal tumor on the recurrent laryngeal or pneumogastric nerves. This is especially the case when the tumor involves the

transverse or descending portion of the arch of the aorta, for the left recurrent laryngeal nerve winds around the arch from the front backwards, while the corresponding nerve on the right side does not. Aneurismal pressure on either of these nerves produces a cough which is loud, short, and croupy, often metallic in character, and associated with a high-pitched voice, and not accompanied by much or any expectoration in the beginning. A cough of this kind in the adult is very characteristic of aneurism, and whenever found it should lead to further investigation. The degree of relief which can be brought to this cough depends on the degree of control we have over the aneurism, which is often slight enough. I have, however, found temporary relief from the laryngeal irritation by the administration of half a drop of Fowler's solution with five grains of potassium iodide every four hours.

*Cough from Pressure on Vagus.*—There is no doubt that cough may be induced by pressure on the vagus other than that which is exercised by aneurisms. A cough of this kind may follow measles, diphtheria, bronchitis, pleuritis, etc.; diseases which lead to secondary enlargement of the bronchial or cervical glands, and a consequent compression of the vagi by these; or to a thickening of the pleural membrane which impinges on the vagus and embarrasses its function. Dr. James F. Goodhart relates the following very interesting case of this kind (*British Medical Journal*, 1879, vol. i, p. 542): "A child eight years old had a severe paroxysmal cough. Parents thought the disease asthma. The child would suddenly start up in bed; his face blue; his eyes staring; all the respiratory muscles in violent action—a picture so terrible that I shall never forget it. He would have five or six of these attacks in a day, and in the meantime some distress of breathing would continue. He became comatose and death supervened. The autopsy showed recent double pleurisy, and bronchopneumonia at both bases. No tubercle. In the right mediastinum there was one greatly enlarged bronchial gland, which had caseated and suppurated in its centre. It was adherent to but did not press on the trachea; the right vagus was firmly adherent to it and surrounded by dense fibrous tissue to such an extent that it was impossible to isolate it even by cutting.

*Cough from Fatigue.*—There is a cough which may be called the "cough of fatigue." Many persons without being subject to any

special disease of the respiratory apparatus, and especially those who possess a family tendency to phthisis, cough when they are tired out by physical or mental work, or when depressed by incidental diseases like colds, headaches, injuries, etc., or by loss of appetite, worry, or by excesses of any kind. Not only is this true of persons who are comparatively well, but those who suffer from respiratory diseases, particularly the phthisical, always cough more when they are fatigued or exhausted from any cause. A cough of this character is in all probability due to excessive waste of nerve force which is reflected on the lungs—the weakest and most vulnerable organs in the body in such individuals—and for its relief the most effective remedies are not physical exercise and outside air, but rest in bed, nutritious food, strychnine, hypophosphites, quinine, and cod-liver oil.

In conclusion I wish to say that you may feel surprised at my failure to recommend the administration of opiates and expectorants more extensively in the treatment of cough, and hence a word or two of explanation may be in order. I believe in the long run it will be found that opiates and expectorants, if given for more than temporary purposes, will nauseate and derange the appetite and disturb the intestinal secretions, and in this way interfere with one of the chief aims of treatment—viz., the building up of the body. It is my purpose, therefore, to treat cough on the restorative plan—rather by elevating than by depressing the functions of the body—and it is my conviction that the best ends are always secured by this method of treatment, except in extreme cases in which opiates must be resorted to.

---

*THE CLINICAL VALUE OF THE CULTURE  
PRODUCTS OF THE BACILLUS OF  
TUBERCULOSIS.\**

---

BY KARL VON RUCK, B.S., M.D.,

Medical Director of the Winyah Sanitarium and Director of  
the Bacterio-Therapeutic Laboratory, Asheville, N. C.

---

In considering this subject we may perhaps best do so by finding answers to the following questions:

1. Have substances obtained from the matured culture of the bacillus of tuberculosis an antagonistic influence upon its life and growth, and can they be distinguished,

chemically or physiologically, from similar substances obtained from the culture fluid upon which no such growth has taken place?

2. If such substances have a therapeutic value, what may we expect to accomplish with them, and what would be their limitations?

3. What available data and experience justify us in the belief that our conclusions as to their therapeutic value are correct?

A study of the evidence which I have gathered in my clinical and laboratory experience, and of the evidence adduced by others in available literature extending over a period of over six years, confirms me in my belief that the first question must be answered in the affirmative.

The details of experiments with the artificial culture of the tubercle bacillus upon bouillon and its subsequent behavior seem to confirm my position in regard to the first question.

When a culture of the tubercle bacillus is made with either an alkaline, neutral, or slightly acid reaction of the nutrient fluid, various degrees of growth of the bacillus take place; under ordinary circumstances the growth is most prolific upon the moderately alkaline fluid, but in subsequent generations the bacillus appears to accommodate and adapt itself to slight variations in the reaction of the media, so that we can obtain a good growth even if the culture fluid is primarily of an acid reaction; but in all such cultures a final limit is reached when no further growth takes place.

If we examine the reaction of the culture fluid upon which the germs appear to have reached the limit of growth, we find either that the primary alkalinity has been diminished, or that the primary neutral solution has become slightly acid, or having started with an acid media, that it has become more acid still; but we find further, that the addition of alkali to the now neutral or acid media is frequently followed by slight renewed growth, while the culture, primarily alkaline, and still alkaline when growth has ceased, does not show further growth and development of the germ if more alkali is added.

No matter how we may originally have started, the growth reaches a limit, and no addition of alkali gives any further aid.

If, however, we add new fluid to such full-grown alkaline cultures, renewed growth and development appear in proportion to the amount added. This would go to show that

---

\*Read before the American Climatological Association, at Washington, D. C., May 6, 1897.

the tubercle bacillus naturally grows best upon alkaline media, that an acid is formed during its growth, that the production of the acid checks the growth, but that it is otherwise limited, since the addition of alkali to neutral or acid cultures is effective only for a time, and the growth finally ceases in media primarily and continuously alkaline, the same as in media primarily neutral or acid and subsequently kept continuously alkaline.

The explanation for this could be that the nutrient material contained in the culture fluid has become used up and has been exhausted by the germs, or that something new and different has been formed by the germs, or that other changes have taken place in the fluid during the growth and multiplication of the germs which are inimical to their further life and multiplication.

If we examine a healthy and rapidly growing culture we find the tubercle bacillus as a rule to be well formed and stained, and the condition of which we speak as "degeneration" is not well marked, certainly not predominant.

If, on the other hand, we examine the germs of the ripe, matured culture, we find the degeneration forms not only to predominate, but note only occasionally well-formed bacilli—thus the rapidly growing cultures and the matured cultures differ in that the former contains mostly perfect forms, while the latter contains mostly degeneration forms.

If we transplant from a culture in which degeneration of the germs has obtained its highest degree, we find that for a long period of time the new culture shows but very slight growth, and in some instances in my experiments no growth was apparent after four months; while with transplantations from a rapidly growing culture, in which few degeneration forms are present, the new culture grows rapidly and vigorously, very often maturing in from six weeks to two months.

If we use the bacilli from such cultures for infection of the guinea-pig, the minimum for successful infection requires to be greater from the ripe than from the growing culture in proportion to the degree of degeneration of the germs; and we also find that animals infected with bacilli showing extreme degeneration live much longer and the resulting disease is much slower in its development and course than is the case when bacilli are used coming from a culture in which degeneration was not marked.

In further examining this fluid upon which a culture has reached its full growth and limi-

tation, we find plenty of the original nutrient material present, and that other germs grow upon it luxuriantly; but beyond this we cannot with certainty demonstrate the presence of any recognizable change (unless it is a decrease in alkalinity) or the formation of any new substance.

If we now take the bodies of tubercle bacilli and extract them with glycerin, we obtain an extractive substance resembling in its physiological effects that of tuberculin, but if we first extract the bacilli with ether or benzol and remove their fat, then we can obtain a watery extract which, as I shall show further on, has a favorable influence in the production of at least relative immunity, without tuberculin reactions.

In examining these proteid substances obtained from the fluid of the culture, or from extraction of the germs, chemistry gives us no definite answer, but we find that they differ in their effects as compared with similar substances obtained from the unplanted culture fluid, so that the previously relatively inert substances have assumed new properties during the growth of the culture.

The fluid of the ripe culture when concentrated so as to represent one-tenth of the original bulk is the original tuberculin of Koch, after the bacilli are filtered out. This, when injected in animals and man, causes certain well defined effects according to the dose given, most marked among which are acceleration of the heart action and rise of temperature, and in man a sense of lassitude, often aching in the back and loins, headaches, and nausea.

For such an effect in a healthy man we require doses of from twenty to fifty milligrammes; the symptoms appear in the course of from six to twenty-four hours, and last from a few hours to twenty-four hours. Smaller doses show a correspondingly slighter effect, but ten milligrammes produce as a rule no effect at all in a healthy full-grown person.

If, however, the subject of the experiment is suffering from tuberculosis, even minute doses (ten milligrammes or less), and in some instances in my experience as small a dose as one-tenth of a milligramme, cause the above stated symptoms to be more or less pronounced. The same is true in animals: doses which in the healthy animal cause no disturbance whatever are followed by increased temperature if tuberculosis is present; and upon this peculiarity depends the diagnostic value of tuberculin.

If we ask for the reason of this peculiar

behavior of the tubercular organism to an otherwise non-effective dose of tuberculin, we can offer only theoretical explanations, but all such heretofore proposed by myself and others are not entirely satisfactory.

The actual facts observed are, however, that the tubercular locality shows evidence of marked congestion, and in experimental work with animals we find this, together with capillary stasis and obstruction, and minute capillary hemorrhages in the tubercular organs.

If we inquire into the therapeutic uses of tuberculin we learn that the doses can be so adjusted as to avoid the physiological effects mentioned, and that the remedy can then be increased very gradually until the patient or animal can tolerate comparatively large doses without symptoms or discomfort, producing thereby only local reactions.

Under such use many cures have been established in the human subject, and more recently the Bureau of Animal Industry of Washington has accomplished a cure in bovine tuberculosis by the use of tuberculin.

In the smaller experiment animals, especially in the guinea-pig, an absolute cure must ever be difficult or impossible; they suffer from disseminated tuberculosis from the beginning, and if the tubercular process has been controlled so that little of tubercular tissue is formed or left, the animals die from secondary effects before a final disappearance of all tubercle can be accomplished.

Professor Koch has produced marked curative effects, and others have made similar claims. In our laboratory similar experiments have also shown a certain degree of influence, but in no case have we accomplished an absolute cure with tuberculin.

These observations confirm, however, that tuberculin does contain something which tends to a cure of tuberculosis, and those who have had the greatest experience in its use are very positive in asserting this fact.

Koch, Klebs, Hunter, Trudeau and myself have endeavored to isolate the valuable and curative part of the culture of tubercle bacilli with varying degrees of success.

The Klebs modifications have given the best results, especially in so far that the one he calls "Antipthysin" does not produce fever even in large doses, whereas tuberculocidin and Hunter's and Trudeau's products seem to contain more or less fever-producing substances.

Under antipthysin, with which I have had experience in the treatment of several hun-

dred cases, some of which I have heretofore reported, the best clinical results have thus far been obtained; and while I have not been able to fully confirm the claims made by its author as to its value in the animal experiments, although most painstakingly repeated during the last year in my laboratory, and while the claims made by its author "that antipthysin kills tubercle bacilli *in vitro*" proved incorrect in an experiment started by himself in our laboratory shortly before he left, and of which I have noted the results, I have not the slightest doubt of its clinical value and its influence upon the purely tubercular process.

The failure to kill tubercle bacilli *in vitro* by their immersion in antipthysin by no means proves that under continued use of the remedy the germ is not adversely affected in our patients; neither must the action be direct, as it scarcely can be under the small doses which prove effective; on the contrary, it is much more probable that the action is only supplementary to the natural antitoxic and germicidal action of the living tissues, especially the blood.

As to the mode of action of these as of many other remedies, we can at most offer more or less plausible theories; surely no one is in a position to offer conclusions. We are not prepared to do this even as to the action of mercury in syphilis after many years of its use. The small dose effective cannot be directly germicidal, and yet under its continued employment syphilitic lesions are influenced so that they disappear.

Under the clinical use of antipthysin or tuberculinum purificatum I and many other observers who expect to eventually report their work independently, or have already done so, have seen areas of dulness clear up and return to normal conditions, the abnormal respiratory sounds giving place to normal vesicular respiration with corresponding improvement in the general condition of patients and disappearance of symptoms—a result in tubercular disease of the lung entirely unique in all past experience.

Without the use of this remedy, or of tuberculin which preceded it, I have never witnessed such local changes, and if the remedies under which only we observe this are not responsible for it, there would be no other explanation than that these observations are always coincidences, and that the physical phenomena which we observed to disappear were due to recent acute pneumonic processes, congestions, or edema com-

plicating the particular case. That this was not the explanation I am quite sure, because in many instances there had been at no time any acute inflammatory condition in the lung, and the cases presented the usual evidence of tubercular disease.

I must, however, here point out that these favorable and unique local changes do not by any means always include the entire lung portions involved, and that localities where the physical signs justified the belief that the lesions were old and probably due to fibroid or caseous changes with or without cavities showed often but slight or no improvement.

My impression under most careful records at each examination has been that localities the seat of more recent extension of the disease cleared up, whereas the older lesions showed little or no influence.

In many early-stage cases where the disease was not extensive the physical evidence disappeared entirely; in other cases where both lungs were involved the side showing the slighter abnormal percussion and auscultation phenomena cleared up entirely, the more involved side only partially, and this was the case with all patients which were treated with the remedy under the auspices of the New Orleans Commission a year ago, and which justified those who examined the patients to say of them, as I say of my own cases, that they never before witnessed such results.

While I am of course unable to say what the total of my clinical results would have been had I not employed the remedies under consideration, the results have greatly improved under their use, and the last report made by me of the work done in the Winyah Sanitarium\* shows twice as large a percentage of cases apparently recovered, or greatly improved, as I was able to obtain prior to the time when I first began the use of crude tuberculin in selected cases.

I cannot appreciate that my clinical material has on the whole been more favorable, nor have I made other important changes in the treatment and care of my patients. I have then as now recognized the importance of dietetic and hygienic measures and of climatic treatment, and have conscientiously insisted upon them at all times with every patient who has come under my care; and while I am well convinced that without such a course and the advantage of having my patients under more constant professional control the results would have been materially changed, I am equally convinced that the addition of these remedies has been a great help.

This clinical experience is further confirmed by bacteriological examinations of sputum from cases under treatment, in most of which a marked degeneration of tubercle bacilli was observed to occur in from four to six weeks' use of the remedy; in many the number of germs was materially diminished; while in some cases they as well as the sputum disappeared entirely.

In all cases sputum examinations were made before the treatment was begun, and the slides were preserved for comparison.

I am well aware that degeneration forms of tubercle bacilli are often found in tubercular sputum, and even in cases in which the disease pursues an unfavorable course—indeed, without the use of culture products we find these forms, most frequently in patients who are making rapid progress toward recovery, or who are nearing a fatal issue.

With the remedies under consideration I have noted the gradual increase of degeneration forms quite uniformly in *all* cases, until in many slides not a single well formed bacillus could be demonstrated, so that in some instances it was a question whether the distorted and nearly coccus-like form was a tu-

\* This report of 182 cases treated at the Winyah Sanitarium at Asheville, N. C., is published in the THERAPEUTIC GAZETTE for May, 1896, in full, showing the following:

#### RECAPITULATION OF RESULTS.

CLASS.	No. of Cases treated.	Apparently Recovered.		Disease Arrested; Greatly Improved.		Improved.		Not Improved.		Grown Worse or Died.		Corresponding to
		No.	Per cent.	No.	Per cent.	No.	Per cent.	No.	Per cent.	No.	Per cent.	
A	32	26	81	5	16	1	3	0	0	0	0	Early stage.
B	74	26	35.1	25	34	17	23	3	4	3	4	Middle stage.
C	76	7	9	26	34.2	11	14.4	3	4	29	38.4	Last stage.
Total (all cases)	182	59	32.4	56	30.8	29	16	6	3.3	32	17.5	All stages.

bercle bacillus at all—while at the same time the number showed a steady decrease until in the most favorable cases none were found at all—an experience quite different from that in which a few of the bacilli show a similar condition.

This almost regular and uniform observation causes me to entertain the thought that the degeneration stands in relation to the remedy; occasional exceptions were noted, however, but they could be accounted for in almost all cases.

A recent contradictory observation in a case may be of interest. The patient had progressed most favorably in all respects under the use of tuberculinum purificatum; the sputum, after having shown degeneration and decrease of the number of tubercle bacilli, had become very slight in quantity and contained no bacilli whatever when last examined. Thereafter the patient began to show some rises of temperature, first slight, but gradually increasing, lost her appetite, and diminished in weight; the cough also increased; but locally the most painstaking examination furnished no clue for several weeks as to the cause of this unfavorable change.

There was, however, a small area below the clavicle which had been undergoing no change whatever from the first examination to the last; the percussion note there had always been flat and the respiration bronchial. In this area moist sounds began to appear, and under an increase of the fever and the cough the patient suddenly discharged several large mouthfuls of muco-purulent matter tinged with blood, when an amelioration of the symptoms took place. In this sputum we found well formed and stained tubercle bacilli in great numbers, and the small dull area spoken of showed now every evidence of a cavity.

As to the explanation of this experience there can be no doubt that the dull locality which had remained uninfluenced was the seat of a caseous mass more or less encapsuled; that this caseous mass softened and absorption from it gave rise to fever; that the increase in cough was due to local irritation; and that the free expectoration coincided with the discharge of the cavity into a bronchus.

That the discharged liquefied, caseous material contained tubercle bacilli would be most natural, for it is not to be thought of that the remedies employed could possibly have reached or influenced these germs in the encapsuled dead tissue entirely removed from the circulation.

In this matter of degeneration observed in sputum I would however not wish to be too positive, and I invite other observers to study the subject. Its occurrence I am sure of—that is to say, we observe a difference in the appearance of the germs from a regular well defined bacillus; we note a granular type, shorter and club-shaped forms, until finally an extreme stage is reached, which has nothing but a coccus-like appearance, perhaps slightly elongated, and more or less perfectly stained.

We have a further confirmation of the clinical value of these culture products in their effect upon lupus and other tubercular processes which are accessible to direct inspection.

The numerous cases of lupus which were recorded by most competent observers as having been favorably influenced or cured with the injection of tuberculin give unmis-takable testimony; the only difficulty was that although lupus could be brought to heal and cicatrize under its use, the effect was rarely a permanent one; after varying periods of time new manifestations became apparent in and adjacent to the cicatrized tissue, and the disease recurred.

Discouraging as this experience was, it nevertheless demonstrated the curative influence and the direct specific effect of the remedy, because we have no other substance which we can inject in the patient's back or arm remote from the local lesion and obtain the slightest influence upon lupus or any other tubercular process.

For these relapses in lupus, as for the incomplete or partial effect of the culture products upon other tubercular processes, there are undoubtedly good and sufficient reasons, if we only understand them. One of the reasons is obvious, and might have been recognized *a priori* as an insuperable limitation, namely, the non-vascular condition of all tubercle, the aggregation of minute tubercle into larger ones, and these into small or large nodules, their caseous degeneration, and the consequent inaccessibility of such isolated or aggregated tubercle to the circulation. Such tubercle could only be reached by penetration of the remedy upon the principle of osmosis.

The larger the tubercle and the more advanced it is in degeneration, the greater is the probability that the contained tubercle bacilli are effectually protected from the influence of remedies which are thus to reach it through the blood, and if in addition we

remember the formation of new cicatricial tissue upon the periphery of tubercle, the frequent complete obstruction of blood and lymph channels in the vicinity of tubercle, and even at considerable distances from it, we need not wonder that the results from treatment with these products have as a rule been only partial, and have not met the hopes of those who, in their enthusiasm over the primary evidence, forgot all their pathology and expected that Nature had reversed her laws in the production of a veritable miracle, and that this perihelion of blind faith was of necessity followed by the aphe-  
 lion of skepticism.

I have, however, no doubt that the observation of the toxic effects of crude tuberculin added also to the disappointment, and it was natural to reason that if the remedy could not as a rule produce a permanent cure, it was unjustifiable to incur the risks which appeared at times quite serious under the large and actually injurious doses of tuberculin, and the forced increase of dosage, by which it was hoped to compel better results.

In other local tuberculoses accessible to inspection we may also remember the good and at times brilliant results which were observed in the superficial tubercular affections of the larynx, and more recently the observations of favorable results in tubercular ulcers of the nose, the eyelids, the ear, and upon the integument, by the use of purified tuberculin when only locally applied.

I myself saw the complete healing and cicatrization of a recent tubercular ulcer upon the lower lip of a patient far advanced in pulmonary tuberculosis, and in which no other treatment than the local and hypodermic use of purified tuberculin was made use of. All who have seen such ulcers in advanced and exhausted cases of consumption know very well that they never heal, but tend to undermine the integument and to enlarge indefinitely until the patient dies.

The clinical value of the culture products, especially of the purified preparations, is further manifest in the control of the fever, which we observe in the early stages of pulmonary tuberculosis at a period when the elevation of temperature can be presumed to be due to the absorption of the toxic products of the germs only.

In the more fully established disease, where we have also absorption of liquefied and decomposing organic substances from necrotic tissue and from suppuration, the cause of the fever becomes very complex, and the influence

of the purified culture products in its removal is then at best only partial.

Unless in acute miliary tuberculosis the purely tubercular fever is very moderate, rarely exceeding 100° F.; quite different from the hectic and septic fever in advanced cases, which would undoubtedly exist and continue even if all tubercle bacilli could be removed from the diseased organism.

While the tubercle bacillus is undoubtedly primarily responsible for the lesions which subsequently cause and maintain fever, it must be readily understood that when the tissues have degenerated, softened, and liquefied, when they have become necrotic, when other germs have gained entrance and have caused suppuration, the substances which are now being absorbed have no direct connection with the tubercle bacillus; that they are the products of decomposing organic matter, and produce the fever, emaciation, night sweats, and exhaustion, no matter whether the tubercle bacillus or some other agency has primarily been responsible.

This we should also have known *a priori*, and we should never have been disappointed when we realized the true relation by experience.

Such fever we cannot hope to remove by the use of tuberculin, or by its purified modifications, and in estimating their antagonistic properties to the bacillus of tuberculosis by their influence over fever we must not select such cases for the basis of our investigations, but rather choose very early stages of the disease, where no such secondary and tertiary causes are usually at work.

But even in these so-called early stages we are occasionally liable to overlook the presence of such secondary causes, as for instance when the lung affection is secondary to a breaking down of a bronchial or mesenteric gland and when it is possible that absorption from it continues to deliver pyrogenic products into the circulation.

Careful study and observation enable us, however, as a rule to distinguish between fever due to secondary causes and effects and that due to the purely tubercular process, which latter alone can be expected to be influenced. That it is favorably influenced I have every reason to believe, having almost uniformly witnessed the advent of a normal temperature in the course of the first month's use of the purified products in all such uncomplicated early stage cases.

In cases where the fever was probably due to the absorption of products arising from

degeneration and disintegration of tissue these remedies have as a rule shown a mitigating influence, but other measures were necessary and were employed, under the combination of which I have been able to frequently conduct cases to an entire cessation of fever as well of other symptoms; while unfortunately in a number of far advanced cases the disease did not appear to be influenced sufficiently to make any difference in the final outcome.

A case showing the influence of purified tuberculin upon the local lesions, the fever, and the general condition of the patient, quite recently observed, may be of interest, and it also shows the value of the remedy for clinical diagnosis, and may serve for an example of cases in which we can hope for more uniform favorable results.

Mrs. B. had been in good health until last August. She gave no tubercular family history. At the age of eighteen she had a severe cough lasting four or five months, under which she had some fever, lost flesh, and grew weak; from this she recovered perfectly, and had no trouble with her lungs until last summer.

She came under my care last October, complaining of a slight hacking cough and a constant sense of exhaustion and fatigue. Her nutrition was still good, appetite fair, all functions except the heart action appeared normal. The heart showed no organic disease, but the slightest exertion caused an increase of the pulse-rate of forty to eighty beats to the minute; indeed the pulse was several times found so rapid after ascending a flight of easy stairs that it could not be counted.

Examination of the chest showed slight relative dullness of right upper lobe, both anterior and posterior; neither was the left apex above the clavicle fully resonant. On auscultation there was harsh respiration with prolonged expiration above and below right clavicle and over supraspinous fossa; on the left side rough inspiration with prolonged expiration in the same localities, and a few fine crepitant râles were also noted in left supraspinous fossa. The sputum was mucous and contained no tubercle bacilli. Her temperature showed slight elevations from the normal toward evening, but at no time from October to January did it exceed  $100\frac{1}{2}^{\circ}$ .

The diagnosis was "probably tuberculosis," with recent extension to the left side.

The treatment consisted in general hygienic and dietetic measures, systematic climatic

treatment, and the use of the pneumatic cabinet with inhalations; the latter were continued for about six weeks, when the cough had disappeared.

For external reasons purified tuberculin was not employed until January, when after repeated examinations the local condition did not show any change whatever, and the temperature had shown a slight tendency to an increase. Maxima of  $100^{\circ}$  F. and over became more frequent in December, and the duration of elevation above normal had increased from a few hours in October to six or more hours each day.

On January 6 I began the administration of purified tuberculin in doses from  $\frac{1}{10}$  to  $1\frac{1}{2}$  cubic centimeters daily, which was continued to February 10. There had been no rise of temperature since January 20, the pulse grew slower, and exertion had much less effect upon its frequency; the sense of exhaustion rapidly disappeared, and her general condition improved in every way; she gained five pounds in weight.

Locally, examination showed no longer any relative dullness below the right clavicle, nor supraspinous on the right side; above the clavicle, however, the percussion note was unchanged, and continued relatively dull. Auscultation above the clavicle showed no change; on the left side the respiration, while not yet ideally vesicular, had lost much of its rough character, and the crepitant râles disappeared.

Although the sputum contained no tubercle bacilli we could scarcely expect to find them in this stage of the disease, and the diagnosis of tuberculosis was not impaired on that account; indeed no other diagnosis seemed admissible, and the result of treatment with purified tuberculin confirmed it.

The conditions which for three months remained uninfluenced quickly yielded to its use, with unmistakable changes toward normal conditions in the abnormal phenomena elicited by physical examination, and a prompt cessation of the attending fever.

If I am correct in my assumption that the lung symptoms at the age of eighteen were due to a circumscribed tuberculosis of the right apex, from which a relative recovery occurred at that time, and that the disease became again active and extended both in the right apex and to the left apex last summer, it is not likely that the relative dullness nor the harsh inspiration and prolonged expiration above the right clavicle will entirely disappear, these being undoubtedly due to

fixed structural changes which occurred in the course toward recovery in the first attack.

If I am further correct that from the right side the disease extended locally and also to the left side, there must have been some liberation of tubercle bacilli in the right apex, in connection with softening and absorption of caseous tubercle; and if more encapsuled caseous tissue is now there a recurrence of such an accident is possible in the future, for it is not probable that the tubercle bacilli therein contained can be reached by the remedies at present employed, and which at most can only bring about the state of affairs which existed prior to the extension. Such a result will undoubtedly be accomplished, and when accomplished we shall have done all that in reason can be expected.\*

The claims for the serum from animals treated with the culture products of the bacillus, with the view of producing immunity, furnish additional evidence that the culture contains curative substances.

Maragliano has worked in this direction for a number of years, and his persistent efforts deserve great credit; he was followed in France, and subsequently in this country, by similar efforts, and from the reports which I have seen within the last year Maragliano seems to have made advances in this direction which we cannot ignore, and which justify one in the hope that serum therapy will still be available in tubercular disease either alone or in combination with direct culture products of the germ.

In the culture of the tubercle bacillus we have on the one hand the products of its vegetation and on the other the bodies of the bacilli, which themselves contain curative substances, especially such as tend to the production of immunity.

Under the suggestion of Professor Klebs we injected dead tubercle bacilli in guinea-pigs in the fall and winter of 1894-5 and found, indeed, that the animals so treated showed a relative degree of immunity; but owing to the very limited absorption the work was given another direction after Professor Klebs took charge of our laboratory, chiefly in the use of extractives from the bodies of tubercle bacilli.

Their solution proved extremely difficult; a glycerin extract proved less efficient than expected, and the results from its use, although at times somewhat encouraging, did not jus-

tify any positive claims. Extracting them with ether and alcohol, Professor Klebs obtained quite unexpectedly two fats—one very soluble and of a red color, the other with a much higher melting-point, and of a white color.

When extracted the two fats separate and both saponify, so that I can here show you the two forms of fat and the soaps which we have made. The germs when deprived of their fat lose their peculiar tinctorial properties.

Other extractives were thereafter made with the production of a nuclein, and with the latter some experiments were made upon animals, which also proved unsatisfactory.

This status had been reached when our relations with Professor Klebs ceased; but the work was continued under my direction by Dr. Dunn, who had carried out the experimental details with Professor Klebs before.

After extracting both fats with benzol, drying and powdering the germs, we found that larger quantities of extractive matter could be obtained by prolonged maceration in distilled water over a warm water-bath, but we finally arrived at a stage where no appreciable quantities were longer obtainable.

We next extracted with glycerin and water, and thereafter we added a small percentage of sodium hydrate to the water and again obtained larger amounts of extractive matter by both methods; this finally also failing we acidulated with hydrochloric acid, and again obtained extractive substances.

All these substances were collected separately, and at the end we had but a minute residue of the broken up bacilli, which we believe to be chiefly cellulose.

With these combined substances we undertook animal experiments with the view of determining their value in producing antitoxic and bacterial immunity. While not yet completed I can say that our control animals are dead long ago, and that those of the treated animals which received the greatest amount appear to live much longer, and are progressing most favorably.

A series of larger animals—goats—were in the meanwhile injected with the products of the whole tubercle culture, according to Maragliano, and after following for six months the injections exactly after the published method of Maragliano, serum was taken and compared as to its antitoxic effect with some of Maragliano's serum purchased from his agents in this country, with the result that both specimens of serum showed antitoxic properties as claimed by Maragliano, the

\*This patient improved further as anticipated, left lung becoming entirely clear, with an additional gain of six pounds in weight.

animals surviving the minimum fatal dose of toxins, whereas the control animals died within forty-eight hours.

To further increase the effect we now continue the injections according to Maragliano, but add increasing quantities of the aforesaid extractives of the germ, while in the meantime the therapeutic effect of the obtained serum and that of Maragliano is being tried on guinea-pigs.

Two years ago Professor Klebs used Paquin's horse serum in a series of animals for its curative influence, with however entirely negative results. Concluding that the serum was impure we made serum from the horse ourselves by Paquin's method, but it proved equally inefficient to influence the tubercular process.

The Paquin serum differs, however, from that of Maragliano in the method of preparation in essentials which would *a priori* justify the expectation that the latter would be more efficient.

In two series of animal experiments, involving the use of over one hundred guinea-pigs, the relative value of antiphthisin, of tuberculinum purificatum containing some of the toxic and the extractive substances of the bacillus, also of Paquin's serum and of Vaughan's nuclein, was sought to be determined.

In the first series the infections were made with large numbers of highly virulent germs, and treatment proved of no influence excepting that the animals which were treated with the purified tuberculin gave better results in living longer than all others, and showing on the whole less advanced and more reparative changes when examined post mortem.

In the second series the number of bacilli used for infection were less, all the animals lived longer; the pigs treated with Paquin's serum and those treated with nuclein died first, and before the controls; there was, however, the interesting fact that the nuclein pigs did not emaciate, and were quite fat when they died. Again, the pigs which were treated with the purified tuberculin, as above stated, outlived all others, and showed the least pathological changes post mortem. (I could at that time obtain none of Maragliano's serum for comparison.)

This is as far as Dr. Dunn and myself have gone in the experimental work with serum, and I gladly acknowledge our indebtedness to Professor Klebs for instructions and help received during his connection with our laboratory, without which we could not have

gone on as well and done the work free from errors which has been accomplished within the last year.

What the ultimate outcome in the production of antitoxic serum and antagonistic germ products will be, or what we will accomplish in the production of bacterial immunity, whether through germ products directly or through serum, our work does not show entirely, but that it will be accomplished in one way or the other I have every reason to believe.

The purified culture products having given me such satisfactory therapeutic results in human tuberculosis, and being so peculiarly free from all reactions and unpleasant complications, I have not felt justified to use the serum or the tubercle bacilli extract in the treatment of my patients, nor shall I do so until my experimental work has progressed further and shows their superiority, or until we have unquestionable therapeutic evidence from reliable sources in a large number of cases.

For experimental work I shall be glad to furnish specimens of the serum we made after Maragliano, and which appears equal to it in all respects, or the extractive substances of the bacillus which we have produced.

From the foregoing considerations it appears, however, that we are obliged to conclude that the culture products of the tubercle bacillus, especially in the form of antiphthisin, purified tuberculin, and the extracts of the bacillus such as I use in my clinical and experimental work, have an antagonistic influence to the bacillus of tuberculosis and to its toxins, and that these products have peculiar physiological and therapeutic properties and are of real value in the treatment of tubercular affections. It appears, further, that their effect is proportionate to the accessibility of the remedy through the circulation by osmosis to the localized tubercle, and to the degree of immunity which is produced during their administration.

Clinically, we have learned that the purified products are absolutely safe and free from the toxic properties of crude tuberculin, that they can be given in any stage and phase of the disease without incurring danger or even discomfort, and that while the results obtained in advanced cases are frequently only partial, and at times entirely negative, in the early stage these remedies are valuable and attended with unmistakable curative effects of a nature such as we have not witnessed from any other remedy.

I presume that it would be more satisfactory to you if I could have presented all the evidence that has been accumulated in the course of six years for and against the belief which I entertain; if at the same time I could have shown you my views on all that pertains to tuberculosis, particularly to its etiology, pathology, and its course toward recovery, or toward a fatal issue, and the manifold external and internal influences which are at work in favoring one or the other result, all of which would aid you in following my method of discipline in the examination of the evidence and would help you in testing the logic of my conclusions. This is necessarily impossible, implying as it would a voluminous book instead of a short essay.

Unable to present such voluminous details, I could only indicate to you in a more general way the character of the evidence; but I may say that in examining it I have endeavored to make ample allowance for unconscious personal bias which, if it exists in my case, must necessarily be in favor of the remedies, for who in search of them, and in the hope that a real advance has been made, could help preferring a confirmative answer which would imply the mitigation, restriction, and more ready cure of a disease with a mortality such as we see in tuberculosis? And who is there that could repress feelings more or less strong which make him eager for success?

These feelings, although thoroughly humane, nevertheless become the cause of a natural bias, and stand in the way of the necessary calmness by which one is enabled to recognize or infer one truth as well as another.

When the evidence is simple and direct, and the subject an uncomplicated one, an undesired truth is readily recognized and compels admission; the necessary mental discipline for its recognition is less; but when as in the present instance the evidence is often obscure and largely circumstantial, and the subject greatly involved, it is frequently possible to offer some other explanation for what we see and believe to stand in relation to the responsible causes and observed effects.

Recognizing these difficulties I have endeavored to be on my guard at all times. I have examined all other possible explanations of the observed facts and results, and have tried to accept only that which appeared conservative and rational in accordance with the evidence; but for such a course a much stronger paper could have been written.

Such being the case, I hope from my hearers who may wish to differ with me an

equally candid consideration, and the recognition of the possible existence of an *opposite bias* which may have resulted from past disappointment with new remedies, from theoretical considerations without evidence, or with insufficient evidence, or from insufficient appreciation of the complexity of the subject.

I hope to have at least justified the conclusion that the field of bacterio-therapeutics in tuberculosis is a promising one; that something of real value has already been accomplished; that past experience points to a contained truth, which it is an advantage to recognize, and which we must further strive to obtain in its purity.

I am confident of progress and improvement in phthiso-therapy; bacterial products, especially the extractive substances of the bacillus, will play an important part. But I cannot believe that we shall reach a stage where we can resuscitate, and bring back to the normal, tissues which have so far degenerated that their state is incompatible with systemic life; much less that we shall be able to remove dead tissues artificially from the living organism by other than mechanical procedures. Such tissues must ever undergo the natural fixed changes which the peculiar existing conditions make necessary; they must be reacted upon, and in turn react upon their immediate vicinity and upon the entire organism. These reactions not only influence the destiny and final disposition of the degenerated tissues and of the foreign dead tissue, but they also determine more or less the ultimate result.

In considering the often apparent insufficiency of curative influences, we should bear in mind that the true and full pathological changes and their advance toward irremediable conditions, or toward conditions of greater peril to the patient than we supposed to exist, are not exactly known in the living subject, and that our expectations would often be modified if we could know the true relations in the individual case.

Appreciating this, we are admonished to leave nothing undone to bring our patients under the most favorable influences in the earlier stages of the disease, knowing that then the pathological changes are necessarily less formidable, and by doing this to reduce more and more the number of advanced cases who come under our care at a time when their treatment is nothing more than a justifiable experiment, in the frequent failure of which the remedies employed are not to be condemned on account of natural limitations.

## Leading Articles.

### THE USE OF OTHER DRUGS THAN DIGITALIS IN CARDIAC FAILURE IN ADULTS.

It is not the intention of this article to discuss the value of digitalis nor the occasions on which it fails in the treatment of heart disease, although it is a noteworthy fact that in those cases in which there is true fatty heart, and in some instances of dilatation, or in the true senile heart in which the organ seems to be inherently feeble, digitalis fails to do good, either giving no relief at all or else causing more discomfort than existed previous to its administration. Under these circumstances the physician who finds that his chief standby has failed him sometimes feels at his wit's end as to what he should prescribe for his patient, for often in these cases nitroglycerin with or without digitalis also fails to be of benefit, probably because arterial tension is already so low that its still further reduction by this drug increases the discomfort of the patient. Under these

circumstances we believe that the continuous administration of full doses of tincture of nux vomica, or it may be of strychnine, affords the best treatment which we can resort to. Under its influence the valvular sounds which have seemed feeble and indistinct become more well defined and clear, the arterial tension is raised, and the general tone of the vascular system seems to be improved. The doses for the adult, unless there is some contraindication to such large ones, should usually be not less than ten drops and often as much as twenty drops of the tincture given three times a day, and should there be any tendency to cardiac irritability some tincture of belladonna or tincture of hyoscyamus may be combined with the nux vomica with advantage, chiefly for the vaso-motor effect. Very often in these cases the greatest discomfort will be at night, and the patient will either suffer from constant dyspnea, or after sleeping a few hours in comparative comfort will waken with a paroxysm of dyspnea which causes him and his friends great alarm. In some instances, it is true, this paroxysm depends upon a gradually increasing arterial tension associated with or dependent upon well marked atheromatous and renal changes, but in other instances, where such changes in the blood-vessels are not marked, and where the arterial tension is not high, and where repeated examinations of the urine fail to reveal albumen or other signs of renal mischief, such a cause for the cardiac embarrassment cannot be depended upon. In many instances these attacks can be put aside by administering with the nux vomica and hyoscyamus that we have named, small doses of morphine either by the mouth or hypodermically. In some instances, too, where it seems advisable to aid the strychnine, or to supplant it by the use of caffeine, and where this drug tends to produce wakefulness, the additional use of morphine not only acts as a circulatory regulator and stimulant, but also tends to overcome this disadvantage in the use of the active principle of coffee. In this manner a patient may be given a comfortable night's rest, or at least not suffer from his symptoms in their most severe form. In the attack itself there is nothing which compares, among the drugs which can be left with the family for immediate use while the physician is being sent for, with dessertspoonful doses of Hoffmann's anodyne, and, when the physician arrives a hypodermic injection of one-tenth to one-twentieth of a grain of strychnine is in the majority of cases strongly indicated.

THE GAZETTE QUOTED EVERYWHERE.

Amongst the very large number of exchanges of the THERAPEUTIC GAZETTE its editors have an opportunity of noticing the frequency with which its contemporaries find its contents of sufficient value to make it worth their while to abstract information from its pages. In the great majority of instances credit is given to the GAZETTE, and we are always glad that such unsought for recognition of the value of our material is manifested.

One particular instance in which credit was not given us as a rule has interested us more than a little. The readers of the GAZETTE will remember that in the issue of June 15, 1896, Dr. Hartzell contributed a paper to the THERAPEUTIC GAZETTE upon Some of the Uses of Resorcin in Dermatology, an article which contained a considerable number of prescriptions. From that time to this we have constantly met in the pages of various medical journals a repetition of these prescriptions. The French journals, as is their custom so frequently, abstracted it one after the other, sometimes giving credit to us, but more commonly to the French journal from which they took it. From France these prescriptions extended to Germany and the various German journals printed them, but few of them giving the reference to the THERAPEUTIC GAZETTE. Finally, one of the great American medical weeklies abstracted them from a French journal to which they gave credit, and now we find these same prescriptions in the *Journal des Praticiens* of February 6, 1897, credit being given to the *Therapeutische Wochenschrift*. The course over which these prescriptions have traveled in medical literature reminds one of that followed by an ocean derelict.

THE INFLUENCE OF DRUGS UPON THE SECRETION OF BILE.

In the *Journal of Experimental Medicine*, No. 1, vol. ii, just issued, is an exceedingly interesting communication by Dr. Franz Pfaff and a student of medicine, Mr. Balch, upon this important subject. Their studies were made upon a woman of thirty-eight who entered the Massachusetts General Hospital and who acquired, as a result of a necessary operation, a biliary fistula. After the patient had recovered from the operation and had regained her normal health, except for the continuance of the biliary discharge from the fistulous open-

ing, Messrs. Pfaff and Balch proceeded to put her upon a standard diet and then to study the changes which took place in the biliary outflow from hour to hour and day to day. Although results obtained from a single individual cannot be used as positive determining factors in the decision of a scientific question owing to the possibility of idiosyncrasy in the individual producing unexpected results, a number of the facts which they have obtained are of great interest and throw considerable light upon previous researches which have been made upon this subject. In the early part of their paper they give a valuable summary of practically all the work which has been done upon the biliary secretion of human beings, excluding whenever possible studies and results which were evidently from their character of little value in the production of scientific results. After careful study of the results which were obtained by these earlier investigators and guided to a certain extent by these conclusions, Pfaff and Balch then proceeded to administer to their patient different substances supposed to possess a stimulant influence upon the flow of the bile. We have not space in this notice to describe the technique and details of their investigation: suffice it to state that the results which they have obtained are quite at variance with those which have been expected, and we find to our surprise, as it was doubtless to themselves, that there was practically but one substance which materially increased the flow of bile, provided that the considerable variations which naturally take place independent of the influence of remedies were excluded. This substance was bile itself. Thus under the ingestion of the woman's own bile, which had been inspissated and made up into pills, the total quantity of bile secreted in twenty-four hours rose from about 500 cubic centimeters in twenty-four hours to nearly 700 cubic centimeters, and when the bile was no longer administered decreased to 440 cubic centimeters.

When ox-bile was given it rose to nearly 800 cubic centimeters, and fell with great rapidity to about 400 cubic centimeters as soon as this substance was no longer administered; and finally when bile salts were given a similar and almost equally marked increase occurred.

On the other hand the administration of calomel produced absolutely no effect, and corrosive sublimate was equally ineffective, no variations from the normal flow being produced.

The only drug which seemed to have any considerable influence beyond the bile which we have mentioned was salol, but even this produced so slight an increase that there is grave doubt as to whether it produced actual stimulation of biliary flow, for the flow only increased from 460 to 540 cubic centimeters. Although these results are surprising when compared to the results which we expect to obtain in the ordinary practice of medicine when calomel and other cholagogues are administered, they do not set themselves as diametrically opposed to the conclusions which have been reached by previous investigators, for it is a well known fact that many of the doses which have been found to produce a marked increase in biliary flow in animals, or in man, suffering from biliary fistula, have no such influence in a healthy individual; and, on the other hand, that some substances which are not considered by the average physician as possessing any hepatic influence have markedly increased the excretion of this hepatic secretion in experimental research. The variations between practical experience and the various scientific investigations which have been made upon cases of biliary fistula seem to make it evident that the mere existence of a biliary fistula in some unknown way modifies the influence of drugs which ordinarily possess the power of stimulating the liver to increased biliary secretion or excretion.

While all studies of this character must be regarded as of great importance and of considerable interest, we cannot help feeling that it will be a long time before practicing physicians will be willing to accept the idea that calomel and similar substances possess no influence upon the flow of bile in the ordinary individual.

Any physician or surgeon who has under his care a case of biliary fistula should utilize it in carrying out a careful investigation concerning this important subject, for it is only by comparing the results obtained in many investigations and eliminating the personal factors which are present in each case, that rules capable of wide application can be formulated for our guidance in practical medicine.

#### THE TREATMENT OF VERTEBRAL FRACTURES.

---

The consensus of professional opinion in regard to the prognosis and treatment of vertebral fractures as expressed by the ma-

jority of text-books is to the effect that these lesions, with the exception of those involving only the spinous processes, are dangerous and life-threatening; that when they are associated with symptoms of spinal compression the prognosis is almost absolutely hopeless; that the best that surgery can do is to treat them conservatively, keeping the patient on a water-bed and allowing Nature, if she will, to bring about union; that manipulations in the direction of reduction are either to be avoided or if employed are to be used only in exceptional cases and with very great care, and as a rule all operative procedures, at least in the early stages of these cases, are to be avoided.

This teaching is mainly based on the results of isolated cases reported singly by a large number of observers. There seem to be but few surgeons who have had an extensive experience with this class of injury, hence the communication of Poller (*Archiv für Chirurgie*, 1897) based on an extraordinary personal experience of upwards of thirty cases, all observed within the last five years, is of more than usual interest.

The cause of the injury in his cases was almost without exception a heavy weight coming from above and forcing the unfortunate ones forward, or as he described it, shutting them up like a pocket-knife. The result of pressure thus exerted was to crush and drive into each other the anterior portions of the vertebral bodies, forcing back the posterior portions in the direction of the spinal canal. The laminae and their processes were often torn from their attachments or otherwise injured. His patients often stated that they heard a crack in the back, after which, from increasing pressure of the descending mass, they lost consciousness. In some few cases the fracture was due to a fall or direct force or from a bending backward.

The lesion was usually situated in the lower thoracic and upper cervical vertebræ, this corresponding to the well recognized rule that fractures are most likely to occur in the regions uniting the more and less movable portions of the spinal column.

There usually appeared at the seat of the injury a more or less distinct hematoma, which did not, however, obscure the deformity, easily felt by passing the finger along the line of spinous processes. This deformity appeared as a space or break in the mid-line, sometimes over an inch wide. Crepitus and preternatural mobility usually could not be detected. Sometimes in transporting these

patients a distinct grating sound could be heard.

Diagnosis was as a rule readily made from the obvious deformity and sometimes abnormal mobility, together with the associated symptoms of injury to the cord. In the absence of typical symptoms, should there be excessive localized tenderness to pressure associated with a history of a crushing force bending the body forcibly forward on the pelvis, it is safe to conclude that the bones have been broken. Should the lesion be confined to the spinous process or posterior part of the arch it is likely that in a few days the patient will be able to raise himself in bed and will do this in spite of the prohibition of the surgeon, thus proving conclusively that no extensive bone lesion is present.

Together with fracture there is frequently luxation, the vertebral body being forced backward or possibly forward, in which case it may be felt on palpation through the abdomen, or in the case of the four upper cervical vertebrae, by examining the posterior pharyngeal wall. The author gives a brief but very clear outline of symptomatology dependent upon the pressure of displaced bone, calling attention to a diagnostic point of extreme importance—*i.e.*, the time at which pressure symptoms develop. Immediate palsy and sensory disturbances point to a primary crushing; these symptoms coming on later in the course of hours or days are suggestive of bleeding or inflammation.

He states that the prognosis of all these fractures involving the posterior part of the arch or the spinous processes alone, without injury to the cord or the nerves, is absolutely good, the patients completely regaining their strength and often the full mobility of the back. Fifteen of what he calls favorable cases are reported.

Treatment on an average was continued for four months. It is interesting to note that one case of priapism and two of vesical and rectal paresis recovered completely.

The treatment consists in placing the patients absolutely at rest in bed, the kyphosis being corrected by carefully applied pads, later followed by extension and the application of Sayre's plaster-of-Paris dressing. In three cases in which the posterior projection was very marked the deformity was reduced under ether. Electricity, massage and douches were employed persistently to restore the muscles to their full tone. Motion was normal after recovery in two-thirds of all cases.

In nineteen cases the fracture was compli-

cated by injury to the spinal cord. Thirteen of these died; six completely or almost completely recovered.

The situation and pathology of the lesions are described and the cause of death noted in the fatal cases. This usually came from the urinary system.

The treatment adopted was forcible extension and reposition of fragments under chloroform. As to the technique of this procedure, the patient was fully anesthetized and extension straps were secured to his head and fastened to a bar which was seized by a powerful assistant; two assistants then seized him by the ankles, and all three pulling together at the word made sufficient traction to lift the patient from the bed. The surgeon with one fist protected by a padded towel then proceeded to knead and force the bone into position. At times the bones could be felt springing into their proper place as impaction was relieved.

It is pointed out that the dangers and disadvantages of this procedure are practically *nil*. Its advantages are evident. Twenty-two of the author's cases were forcibly reduced in this way, and in not a single instance was even partial paresis or anesthesia produced; and in at least one case there was almost immediate restoration of motion and sensation, previously totally abolished.

The subsequent treatment of these cases was most carefully conducted. They were never allowed to move from the bed in less than two months, in the meantime every precaution being taken to avoid bed-sores and prevent cystitis. When it was evident that the bones had become well united the patients were extended daily as for the application of a plaster bandage until they could endure this treatment for from twenty to thirty minutes at a time. A plaster bandage was then applied, and they were placed in a wheeled walking chair, or given crutches. In vertebral fractures the plaster dressing was not applied.

Special caution is given against getting these patients out of bed too soon and against allowing them to begin their work before a sufficient time has elapsed for complete consolidation, since recorded cases show that slow inflammatory processes are likely to be set up followed by softening and great deformity.

The author concludes by stating that in all cases of vertebral fractures with symptoms of compression and forward angulation of the

spinal column immediate replacement under ether is indicated.

This communication of Poller's is chiefly valuable because it will lead us to look more hopefully on cases of fracture followed by symptoms of spinal compression, and aside from operation offers a promising therapeutic measure, which is shown at most to be harmless.

---

## Reports on Therapeutic Progress

---

### IMPROVED METHODS OF TREATMENT IN EYE DISEASES, AND RECENT AD- VANCES IN OPHTHALMIC WORK.

THOMAS BICKERTON of Liverpool writes entertainingly on this topic in the *Liverpool Medico-Chirurgical Journal* for January, 1897. He says in regard to ophthalmia neonatorum if you look through your text-books, you will be at a great loss as to what are the best remedies to adopt. You will find a multiplicity of remedies mentioned, and, acting upon the various suggestions, you will perhaps have tried one drug at one time, and another on another occasion.

In this connection, and as an example of the vagueness of writers in demonstrating to the medical profession the methods of treatment in these cases, Bickerton cites two sentences which are the statements on this subject by a well known author: "Meantime the nurse or attendant should employ some lotion, dropped inside the lids every two or three hours." Again: "The iced compresses should be kept to the eye for an hour at a time, with the pause of an hour, and so on, or even continuously." Now, what are you to make out of directions such as these? Nothing, absolutely nothing; such directions only lead to helplessness and confusion.

In the author's own practice there is one method of treatment for ophthalmia neonatorum which he has never found to fail in curing this disease, even where the patient has been brought with the cornea already actually ulcerated.

The remedy he has found to be so efficacious as to be almost a specific for this disease is zinc chloride. The whole method consists in: (a) the constant application of iced zinc chloride lotion, one to two grains to the ounce, night and day; and (b) the scrupulous avoidance of any interference whatever with the eyelids. If the eyelids show a tendency to stick together a few drops of castor or olive oil dropped on the edges of the lids will

prevent this. Chloride of zinc is one of the most powerful of germicides, but like many other useful remedies it has been overlooked, owing to advertising chemists endeavoring to make money by the discovery of some new and attractive remedy, to the neglect of old, tried, and much more valuable ones. In applying this remedy but little good is obtained by its use intermittently; to derive its full value it must be applied continuously until all discharge has ceased, and for a short time after.

The manner in which he directs his patients to use this remedy is as follows: Procure an ordinary jam-jar, and into it put some chloride of zinc and water in the proportions of two grains of the former to an ounce of the latter; then place this jar inside a larger one, and pack the space between the two with ice. In this way the zinc lotion is kept cold without dilution. In this lotion many pads are kept, and when it is required to change a pad the used one is thrown away and a new pad from the lotion is placed, without being wrung out, directly on the eyelids. Thus the eye is constantly soaked with lotion, the lids are prevented from sticking together, and the discharge has free vent. Chloride of zinc is a most powerful germicide, and it may be used without fear of absorption and the production of general toxic effects.

The micrococci which cause this disease are probably destroyed by the action of the chloride of zinc, the effect of the continuous application of ice in lowering the local temperature being to diminish the vitality of the micrococci, thus rendering them more susceptible to the influence of the chemical reagent, and at the same time, by constricting the blood-vessels, to reduce the local inflammation, and to diminish the amount of discharge in which the organisms thrive.

In giving directions to the nurse as to how often the pads should be changed, the writer tells her "every few minutes," because you will be surprised to find how hot the eye becomes even in this time. This treatment he has found in his own practice to be infallible. He has not failed in a single case since employing it.

By some authors you are told to syringe the eyes well, particularly under the skin. The result of doing so is that the nurse not infrequently squirts some of the discharge into her own eyes, and besides this serious accident, in many cases the eyelids, owing to the extreme swelling, are so tense that they

cannot be elevated without causing much pain and risk of injury to the cornea. The effect of iced chloride of zinc lotion upon the eyes is most gratifying. Instead of the eyelids remaining tense and hard, you will find the skin regaining its normal color and the swelling rapidly subsiding. He recommends writing in red ink across your textbooks the treatment that he has now advocated for ophthalmia neonatorum. He feels certain that if you once try it you will never regret it. But you must make absolutely certain that the nurse changes the pads regularly and constantly, the discharge being extremely deleterious, and only neutralized by constant and fresh lotion. The difficulty occasioned by the lotion running over the patient's face and wetting the bed-clothes is easily got over by having a fold or two of toweling around the neck.

An infant was brought to the outdoor department three months ago. The mother was attended by a midwife, and on the third day the infant's eyes became inflamed, the inevitable poultice was applied, which rapidly becoming cold pressed the lids together, caused retention of discharge, and increased the local inflammation. When brought to the hospital a week or ten days later the disease was at its height, and the case looked unpromising. The zinc treatment was at once commenced, and from the very first application improvement was most marked, the threatened ulceration of the cornea ceased, and the eye was saved.

It may be said by some that the same result would have been obtained by the usual application of nitrate of silver, with a lotion of alum, of perchloride of mercury, boric, salicylic, or carbolic acid, etc. Perhaps so; but Bickerton has lost eyes, even though he treated with such remedies from the very commencement of inflammation, and has never lost an eye since adopting the above method.

#### CLINICAL AND BACTERIOLOGICAL RESEARCHES UPON THE ACTION OF THIOSINAMIN.

According to *Les Nouveaux Remèdes* of January 24, 1897, VAN HOORN has confirmed the studies of Hebra in regard to the action of thiosinamin. The injection of thiosinamin produces a redness and tumefaction of the surrounding skin, and later there is abundant desquamation. During the reaction following the injection the patient suffers from a sensation of heat and tension in the part.

Van Hoorn asserts that thiosinamin is very efficacious indeed in cases of lupus. The ulcers heal and the swelling disappears. The maximum quantity which is employed is three grains. In two women after five months of treatment with only one month's interruption, during which time two to three injections of thiosinamin in alcoholic solution in the proportion of fifteen per cent. were employed, there was loss of appetite, a sensation of fatigue, and general debility, which necessitated the suspending of the treatment. Bacteriological investigations showed that thiosinamin on pure bacterial cultures is not, however, a powerful germicide.

Van Hoorn, however, concludes his paper by once more highly recommending the use of thiosinamin in lupus, but says it is only of value when applied locally.

#### THE TREATMENT OF CONSTIPATION IN INFANTS.

The *Journal des Praticiens* of January 9, 1897, contains a practical article upon this subject: First, it deals with the local accidents which may produce constipation, calling to mind the fact that purgatives should not be given until we are confident that umbilical or other hernias do not exist. It may be, too, that prolapse of the rectum or an anal fissure may be a factor to be considered. It is not to be forgotten, also, that fever and cutaneous eruptions sometimes arise in children as the result of constipation. An important factor to be considered in treating these cases is that of heredity and conformation of the intestine. Children of gouty parents frequently suffer from atonic bowels, and in other cases the intestines and abdominal wall seem to be so relaxed as to predispose to this condition. The employment of sterilized milk also favors constipation, and the administration of farinaceous articles too early in life, by provoking dyspeptic troubles, may either result in diarrhea or constipation. The question of modifying the diet of the child, therefore, is of very great importance. If old enough to receive vegetable substances they should be given Graham bread, which leaves a large residue; the ordinary vegetables such as string-beans and peas, and from time to time mild laxative substances such as manna or cascara, should be given. Frequent exercise in the open air is also a necessity. Very frequently adding a little sugar to the milk, if the child is fed on sterilized milk, will prevent it being so

constipating in its effects. Massage of the abdominal area gently applied for a number of minutes morning and night, the skin being rendered oily by the use of vaselin, is also a method which is not to be forgotten. During the massage the fingers should knead the intestines as much as possible. Castor oil and magnesia, while active in moving the bowels, tend to produce constipation to a greater degree after their effects have passed off, although the author of this article believes that calcined magnesia is a useful substance to overcome dyspepsia and to move the bowel in certain cases. In other instances suppositories and rectal injections produce the best results, particularly suppositories that are made of glycerin. The quantity of liquid which should be used as an injection varies, but ordinarily one or two ounces is sufficient in young children; and if the bowel is not active cold water may be used in place of warm water, and the action of the injection may be increased by the addition of two to three dessertspoonfuls of oil of sweet almonds.

---

#### THE TREATMENT OF THE FEVER OF GASTRO-INTESTINAL IRRITATION IN CHILDREN.

According to the *Journal des Praticiens* of January 9, 1897, GRASSET recommends the following:

℞ Calomel, 1 to 2 grains;  
Sugar of milk.

To be taken in a teaspoonful of milk.

Or, equally well,

℞ Calomel, 3 grains;  
Sugar of milk,  
Benzonaphthol, of each 3 grains.

This to be made into one powder and given every three hours in the milk.

---

#### THE EMPLOYMENT OF DIGITALIS IN PULMONARY DISEASE.

According to an article by BLOCH, as quoted from *Vratch* by the *Journal de Médecine de Paris* of January 31, 1897, he has employed strong infusions of digitalis with advantage in the treatment of pulmonary disease, founding his method upon the statements of Traube and Petresco, who have administered from two to three grammes of digitalis a day. Bloch has given digitalis daily to thirteen children suffering from croupous pneumonia, as follows: To a child of nine months, four grains; to a child of a

year, five grains; to a child of two years, seven grains; to a child of three to four years, ten to twelve grains; to a child of ten years, fifteen to twenty grains.

The writer has never seen any accidents arise nor has he found that the digestive disturbances prevent the administration of digitalis to children. He believes that the remedy is of value in the treatment of pulmonary affections in this class of patients. A reduction of temperature is marked and continuous. The respirations are quieted, and by the administration of the infusion we avoid giving the active principle, digitoxin, which is so apt to produce poisonous symptoms. Bloch believes that the contraindications to the use of digitalis are very early infancy and extreme old age; persons over sixty years of age taking it badly. He believes rightly that these large doses must not be continued for long periods of time, and every few days they must be stopped.

[It is worthy of note in connection with this report that all statistics as to the usefulness of treatment of croupous pneumonia in children, in which death and recovery are used as the signs of value, are useless because the prognosis is almost invariably favorable in the croupous pneumonia of young children. As to the employment of enormous doses of digitalis in the croupous pneumonia of adults, we believe that its routine employment in these large doses is not justifiable.—ED.]

---

#### THE TREATMENT OF FIBROID TUMORS OF THE UTERUS BY ICHTHYOL.

The *Journal des Praticiens* of December 12, 1896, recalls the fact that it has from time to time insisted upon the good results which are obtained by the use of ichthyol in certain cases of urethritis and gonorrheal vaginitis. Recently CHERON has obtained marked benefit from the employment of ichthyol in cases of fibroid tumors which were painful in character, using the drug in the form of a pomade or in capsules. The following ointment may be used:

℞ Neutral glycerin, 10 ounces;  
Ichthyo-sulphate of ammonium, 6 drachms.

If this ointment irritates the vagina the glycerin is to be reduced to seven drachms and the ichthyol to two drachms. Every night he has applied the following ointment to the abdominal walls, with considerable massage, and in the morning has the bowels moved by a large injection of warm water:

- B Extract of digitalis, 1 drachm;  
 Soft potash soap, 2 drachms;  
 Ichthyo-sulphate of ammonium, 2½ drachms;  
 Vaseline,  
 Lanolin, of each 1½ ounces.

After the administration of each meal he gives a pill containing one and a half grains.

#### THE TREATMENT OF DIARRHEA BY DERMATOL.

Dr. CLEMTAL, of Helsingfors, has experimented upon the action of dermatol in sixty cases of diarrhea dependent upon different causes, and in all of them obtained equally good results with those obtained by the use of opium and subnitrate of bismuth. The doses which he gave varied from four to seven grains, four to six times in twenty-four hours. In no case did he observe that the prolonged use of dermatol produced any inconvenient result.—*Journal des Praticiens*.

#### INJECTIONS OF CAMPHORATED NAPHTHOL FOR SARCOMA.

In *La Médecine Moderne* of December 16, 1896, FERNET records the case of a patient aged forty, who ten years before had suffered castration for sarcoma of the testicle and who had developed recently an adenopathy of the subclavicular and mediastinal spaces with obstruction to the venous circulation, particularly the superior vena cava.

Fernet asserts that injections of camphorated naphthol in the neck resulted in complete cure. Later symptoms of glandular involvement of the mediastinum reappeared, and injections of camphorated naphthol were made into the mediastinal glands, the needle of the syringe being introduced through the first intercostal space close to the sternum. This resulted in considerable relief.

[It is difficult to conceive that the diagnosis was correct.—ED.]

#### TRIONAL AS A HYPNOTIC.

The *Journal de Médecine de Paris* of January 31, 1896, quotes GOLDMANN as stating that in his experience trional is much preferable to sulphonal. Its action is much more rapid and certain. Furthermore he does not think that it accumulates in the system as does sulphonal, and that it does not strain the kidneys and intestines in its elimination, and finally that full doses of it are not so apt to produce hematoporphyrinuria as are full doses of sulphonal. He believes that trional is an exceedingly harmless hypnotic.

#### THE USE OF SUBCUTANEOUS INJECTIONS OF ARTIFICIAL SERUM IN ECLAMPTIC ALBUMINURIA.

In *La Presse Médicale Belge* of January 24, 1897, SOLÉ contributes a paper on this subject. He believes that massive injections of artificial serum should be given subcutaneously in all severe cases of toxemia. This method was first employed, he states, in 1855, when intravenous injections of salt water were given to combat cholera, and in 1873 the subcutaneous method was employed by Kartz in place of the intravenous procedure. In 1889 Dastre and Loye presented a communication to the Société de Biologie in Paris as to the effects of saline injections upon animals, and in 1890 Sahli of Berne attained great success in the treatment of a case of uremia by such injections; in 1893 Porak began using subcutaneous injections in eclampsia to diminish the toxicity of the blood-serum.

Charpentier at the Gynecological Congress in Geneva also recommended this treatment. Later Lejars and Tuffier obtained excellent results by similar methods, but insist that the kidneys must be intact if this method is to be of value. Most of these authors have been satisfied with injecting about half a pint a day.

The following case is interesting as an illustration of the use of this method: On December 7 a married woman, aged twenty-six years, and a primipara pregnant seven months, was attacked by severe pains in the epigastrium accompanied by nausea and vomiting, occasional headache, and no visual disturbance. She was somewhat stupid, semi-comatose, and she responded with difficulty to questions put to her. There was edema of the lower extremities, of the abdomen, and of the face, which had been present for about five days. The respirations were rapid and shallow, forty per minute; the pulse small, rapid, filiform, and 160; the temperature was raised. The urine was scanty and contained blood. Rapid analysis showed that it was loaded with albumen, and a more careful examination by means of Esbach's albuminometer showed that there was present three drachms of albumen to the quart. One and a half ounces of sulphate of magnesium and some bromide of potassium and chloral were administered by the mouth, and chloroform was given to the point of slight anesthesia. Professor Kufferath was called in consultation, and by the evening the patient was found to be in deep

coma and remained so three days later. An application of six leeches was made to the mastoid, and the subcutaneous injection of a small quantity of pilocarpine was resorted to. Later on two severe convulsions involving chiefly the face and upper extremities appeared, and inhalations of chloroform with one injection of pilocarpine were resorted to. Forty minutes later a third and general attack of eclampsia resulted, and chloroform was given again. Three-quarters of an hour later a fourth attack came on. This decided the physician in attendance to bring about artificial delivery, and the patient was given twenty grains of chloral and twenty drops of laudanum by the rectum. Shortly after this the patient began having attacks every half hour, but after a few paroxysms they gradually decreased, the chloral and chloroform being pushed. Twenty-four hours after the onset of the symptoms manual dilatation of the os was performed and a female child delivered; but two hours later the coma still persisted, respiration was stertorous, and the albuminuria was still present in excess; there was a febrile temperature, and the pulse was rapid. It was then decided to give four ounces of milk with fifteen minims of ether by the rectum, and this was given on two occasions at hour intervals. Later on one ounce of cognac was also added to this injection and repeated twice. The patient's condition, however, did not improve. On the third day after the attack commenced one pint of normal saline solution was injected into the subcutaneous tissues into the axilla of each side, and shortly afterwards catheterization removed from the bladder almost a pint of yellow urine, although the patient in the preceding twenty-four hours had only passed less than half this quantity. On the following day half a pint of fluid was injected into the left flank, and the urine on being measured amounted to nearly a pint. Later on in the same day another injection of half a pint in the right flank was given, and these injections then followed in half-pint quantities every three or four hours, with the result that at the end of twenty-four hours the patient's condition was much ameliorated; the temperature was not so high, the pulse much better, and the respirations nearer the normal. At this time it was noticed that there was a slight eruption upon the skin of the chest, which the author thinks was due to the elimination of the chloride of sodium. The patient ultimately recovered.

The difficulty in most of these cases seems to be that sufficiently large injections are not

given. One or two quarts can nearly always be given in twenty-four hours with advantage. The liquid should not flow into the tissues too rapidly, for on the one hand absorption would not be sufficiently active, and on the other the kidneys could not eliminate it.

Each injection should be given in a different place from its predecessors. The advantage of this method of administering saline fluid is that it has no difficulties or dangers, that moderate antisepsis only is required, that a vein does not have to be opened, and that there is no danger of air embolism or other forms of embolism taking place.

The suggestion of Bozzolo that the fluid be injected into the pleural or abdominal cavity is even more dangerous than venous injection; furthermore rectal injection gives very slow results and depends largely upon the ability of the bowel to retain the fluid. Solé believes that these injections should be employed not only in puerperal hemorrhage but also in puerperal septicemia, and mentions four cases of the latter condition which were saved by this method. He quotes one or two authorities, however, as stating that acute inflammation of the kidneys is a contra-indication to this manner of treatment.

---

#### THE OPERATIVE TREATMENT OF PURULENT PERICARDITIS.

Bonn reports a case of the treatment of purulent pericarditis and quotes the observations of fourteen others in a recent article in the *Deutsche Medicinische Wochenschrift*. Of these fifteen cases, eleven were men and four women, and their ages ranged from thirty-three years to extreme youth. In three cases the pericarditis was primitive. In one case it resulted from an injury to the chest-wall with infection of the pleura. In another it came on in the course of acute articular rheumatism, and in three as the result of influenza. In five cases it resulted from infection from a suppurating focus, as for example osteo-myelitis. In eight of these fifteen cases paracentesis was performed one to three times; eight patients were cured and seven succumbed to the operation, the death being supposably due to shock. In Bonn's case the operation was performed without anesthesia because of the extreme feebleness of the patient, an incision being made in the third intercostal space about two and a half inches in length, through the tissues of the

chest, and into the pericardium. After the pus had been set free the cavity was packed with tampons of iodoform gauze and a compress applied. The results for good in this case were absolutely marvelous.

The author concludes that in cases of suppurative pericarditis an incision into the pericardium is absolutely indicated, and that under such circumstances an operation is just as obligatory as a tracheotomy or herniotomy when they are indicated.—*La Médecine Moderne*, Jan. 27, 1897.

#### ON THE INTRA-TONSILLAR INJECTION OF CARBOLIC ACID IN TONSILLITIS.

KRAMER is reported in *Schmidt's Jahrbücher* for January, 1897, as having employed parenchymatous injections of carbolic acid in severe tonsillitis, particularly where it was thought there was a tendency to abscess formation. The part is made completely anesthetic by the use of cocaine solution; a sterilized needle attached to a Pravaz hypodermic syringe is gently introduced into the gland, and through this is injected from one-half to one cubic centimeter of a two- to three-per-cent. solution of carbolic acid. This may be repeated once or twice a day. The same treatment has been employed by Höfer in Munich, with asserted advantage.

#### THE TREATMENT OF MALIGNANT TUMORS BY ERYSIPELAS SERUM.

*Schmidt's Jahrbücher* for January, 1897, quotes VON JAKSCH as having made the following report: He has tried erysipelas serum, made according to the process of Emmerich-Scholl, in five cases of inoperable sarcoma. In all cases after the injection there followed a severe chill, high fever, great pain, and in one case severe collapse, and in another acute nephritis. The author does not seem favorable to the further employment of this treatment.

#### AN INSTANCE OF THE UNTOWARD INFLUENCE OF FULL DOSES OF ARSENIC.

Dr. SCHIRLZERN has reported in *Schmidt's Jahrbücher*, January, 1897, having seen a case of a fifteen year-old child of a distinctly neuropathic tendency, with a history of articular rheumatism, who was suffering from chorea minor, the spasm involving the left sternomastoid and splenius capitus. Ascending

doses of Fowler's solution were ordered until very large doses were taken. At the end of thirty-two days as much as two drachms were ingested, when the patient developed herpes nasalis, and a day later a chill and high fever with herpes labialis, and laryngealis and paraesthesia of one side of the head.

#### TREATMENT OF BURNS AND SCALDS WITH PICRIC ACID.

In the *St. Louis Medical Review* of February 20, 1897, THOMPSON contributes a practical article on this subject. He begins by pointing out a fact well known to the readers of the *GAZETTE*, namely, that picric acid has been recommended by French surgeons as being the nearest approach to an ideal treatment of burns. It was subjected by them to several years of experimental use, and their reports have been most flattering. In his official capacity as Dispensary Physician of the St. Louis Health Department the writer has had large opportunities to thoroughly test the value of the drug. His experience consists of the study of some sixty cases—all emergency ones—and they presented a great variation as to cause and condition: they were burns and scalds from explosions of gasoline, gas reservoirs, lamps, contact with electric wires, hot water, hot tar, steam, molten metals, colored fires, etc. In all cases picric acid was used as a local treatment, and it was so agreeable to the patient and so successful from a scientific standpoint that there was no desire to return to the older methods.

Picric acid has long been known and valued as a laboratory reagent. It is one of the most valuable microscopical stains; it is the reagent in Esbach's quantitative test for albumen; and it appears in a pretty sugar reaction. Its properties are as follows: it is a local anesthetic, it coagulates albumen, is astringent and antiseptic. It can be applied in most any manner: the dry powder can be sprinkled on, or gauze compresses saturated with a solution of the acid can be applied; or, if the burn is universal, the body may be immersed in a bath of the solution. For minor burns we find it very satisfactory to allow the patient to procure some of the acid and bathe the surface every few hours or as often as pain returns. No toxic effects come from the absorption of the drug even if it colors the urine a deep yellow.

The acid is not very soluble in water, two drachms saturating a quart; the solubility can be increased by the addition of one ounce of

alcohol to a quart of water. For emergency work any amount of the acid can be added to the water, which being stirred is ready for use. The first and most gratifying effect of the acid is the almost instantaneous relief of pain, even in cases where the epidermis has peeled off, exposing the papillæ to the air. In most cases the pain will be entirely eliminated, and in all it will be reduced to a minor symptom. A remarkable fact is that the acid will prevent blistering if applied soon enough, and it will limit the blistering if it has already begun. The acid is a strong astringent, and it contracts the superficial vessels and consequently checks the escape of serum from them. Picric acid coagulates albumen. If the epidermis is disorganized by the heat the acid will fix it in a firm coagulated layer and healing will take place, as it were, under a scar. Healing under a scar is always a desired method of tissue repair.

The timely use of the acid is a great safeguard against suppuration, because it is antiseptic and because it contracts the vessels, thereby preventing pressure necrosis of the cells.

The effect of the use of picric acid is remarkable, and in the writer's experience of more than half a hundred cases he is convinced that its worth has not been exaggerated. The results are uniformly good; healing will be rapid, with little scarring or deformity.

There are a few practical points to be remembered: In the first place, the blisters which are formed should never be incised—it will expose the naked papilla to the air and increase the pain and danger of infection; they should be punctured and the serum forced out; the epithelium will then collapse on the corium, and rapid subcutaneous healing will follow. It is also wise to let the shreds of clothing which have been burned into the skin remain until the second dressing; the cloth will be burned and aseptized, and it will do no harm by remaining, while its removal can only be accomplished by stripping away the flesh. The cloth will act as a capillary drain into the skin and it will promote a permeation of the acid solution into the injured tissue. At a second dressing the thoroughly soaked fibres can be more easily removed.

It is a very noticeable fact that dressings soaked in a picric acid solution do not stick as fast as other applications; this may be due to the astringent effect of the acid on the secretions.

In handling the solution of the acid the hands of the attendant will be stained a deep yellow color; this unsightly staining can be prevented by a preliminary application of vaselin to the hands, and by a final scouring of them with soap and boric acid.

If suppuration takes place the dressings should always be of gauze or some hydrophile substance. Drainage is most essential. The writer has not experimented with picric acid in the treatment of pus cases and cannot speak of its value in such, but as an emergency first dressing of burns and scalds it has no equal.

#### MERCURIAL ALBUMINURIA.

In *Schmidt's Jahrbücher*, No. 1, 1897, is an interesting abstract of a paper by JULIUS HELLER upon this subject. This investigator examined 8000 specimens of urine derived from 201 syphilitic men, 79 syphilitic females, and 35 persons who were not syphilitic. As the result of the examination of the urine he found albuminuria in twenty-five of the men, and in the women marked albuminuria in four cases. In thirty-five cases of bubo, the urine of which was examined 636 times, a trace of albumen was only found on two or three occasions. The test commonly employed was Heller's. He found as a result of the administration of mercury to these persons that in no case was the albuminuria very marked, but that when nephritis was present and mercury was given albuminuria became much increased.

He quotes Lewin, who has used hypodermic injections 80,000 times with sublimate, as never having seen nephritis result, although he had seen a severe case of hemorrhagic nephritis occur, after the injection of the salicylate of mercury. It seems evident therefore that the bichloride is the preferable preparation for hypodermic injection.

#### ON THE MODERN NEGLECT OF LEECHING IN PRACTICE.

SIR DYCE DUCKWORTH, well known for his able "Treatise on Gout," writes in the *Liverpool Medico-Chirurgical Journal* for January, 1897, under this title. He believes that medicine is now suffering bitterly from a neglect of bedside study as compared to laboratory instruction. Bacteriology is now uppermost, and dominates everything. We gladly welcome all that comes to us in this channel, and should duly apportion it its place in the great

domain of pathology. If we lose our heads we may begin to think just now that all pathology is bacteriology, and that bacteriology covers the whole field of pathology. This, of course, is nonsense. Twenty years ago the danger was that we were becoming stereotyped in the belief that pathology was entirely displayed for us by high powers of the microscope. We now see that that was but a part of pathology, and have relegated the results of such investigations to their proper place in that science. In due time bacteriology will find its appropriate place, and we shall be in face of some further development which may again dominate the views of our successors. These ideas ought to be fairly regarded by us as each new discovery comes up to engross us. We must hold firmly by what we have each acquired, and build up a solid basis on which to rear cautiously worthy and dependable superstructures.

Duckworth is led to make these remarks by finding that the good old-fashioned employment of leeches has been allowed to drop out of our therapeutic armamentarium. So much is this the case that few practitioners are now aware of the value of the practice of leeching, and the pharmacists hardly think it worth while to keep leeches. Not many young practitioners could state correctly the amount of blood withdrawn by an ordinary leech, and a common view is that local blood-letting is generally unnecessary, and can be dispensed with in favor of some analgesic or antipyretic tabloid form of drug; further, that bleeding is a lowering and devitalizing process, and has no power in modifying the inflammatory conditions as now explained by the modern laboratory pathologist. Familiarity with local blood-letting enables the author to deny these assertions, and an ounce of practice is worth a pound of theory. He often teaches that when common sense and practice of medicine do not agree, he is sorry for the principles that determine the latter. He believes that ophthalmic surgeons still testify to the beneficial use of leeching in early inflammatory conditions. General physicians and gynecologists have lost this part of their art, and their patients are the sufferers in consequence. For acute pain such as ushers in acute pleurisy, pericarditis, and peritonitis, from any cause, there is no remedy so certain to afford prompt relief as local leeching. We may thus often withhold opium, and leave other symptoms to declare themselves without the masking effects of this drug. Two or three leeches will often accomplish this

result, and the blood lost hardly exceeds one ounce. In early typhlitis we may resort to this practice, and in many local forms of painful pelvic peritonitis. Much mischief in the future may thus be averted.

In cases of cardiac dilatation in an advanced stage, with hepatic and general venous engorgement, leading to respiratory distress, gastro-enteric symptoms—a veritable “agony”—the application of half a dozen leeches to the epigastrium is often of singular benefit, and brings prompt relief sooner than any other remedies he is acquainted with. In the face of facts such as these, to be certified in daily clinical practice, we may well ask why such a valuable method has been allowed to pass into desuetude. The answer is that other methods have come into vogue, all inferior really, but founded on more modern views of pathology. These methods do not stand the test of actual practice when duly compared with the older—call it “rule of thumb” or “routine” practice of our forefathers; but they have not been carefully compared, but allowed to drop out in the belief, perhaps honestly maintained, that a “more excellent way” had really been revealed to us in accordance with modern light.

With this plea in favor of this much-neglected method he closes his remarks, and hopes that he has done some good by expressing them. It is too often forgotten that our duty as physicians is to heal our patients if we can; and if we cannot bring back health, at least to alleviate to the utmost all suffering and discomfort as readily and certainly as we can.

In adopting any new method of treatment we have to keep our heads, to weigh most carefully the merits of such practice, and compare it honestly with the ripe experience and wise teachings that have come down to us from those who have preceded us, remembering that “our forefathers were not all fools,” and that the full light of midday is not perhaps yet shining upon us, even at the close of the nineteenth century.

#### SPRAYS AND INHALANTS.

BISHOP of Chicago in the *Medical Standard* for February, 1897, tells us that having devoted considerable time to the investigation of inhalants he has endeavored to arrive at definite results. We know well the action of nitrate of silver or sulphate of zinc when applied to mucous membranes, but accurate studies have not been sufficiently devoted to

the physiological action of the large number of inhalants offered for our use. It is worth while to consider briefly the results we may expect to obtain from a few of our most valuable medicaments that are convertible into sprays and vapors. Before applying local remedies to diseased surfaces their actions should be understood for the same reasons that no internal medicine should be administered without fulfilling a special indication for its use.

Before applying remedies to the throat and nasal cavities for the purpose of promoting a healthy action in the mucous membrane it is generally necessary to wash out those cavities with alkaline and antiseptic solutions in order to free the surfaces of discharges or crusts that defend the membrane from the action of our inhalants. Dobell's solution is the one most universally used. It consists of bichlorate and bicarbonate of sodium, 1 drachm each; carbolic acid crystals, 12 grains; glycerin, 2 drachms; water, enough to make 8 ounces. Seiler's antiseptic solution is also satisfactory, and is easily and quickly made by dissolving one of the tablets in two ounces of pure water. These solutions loosen and wash out the secretions and crusts so that the diseased membrane itself can be reached and medicated by our sprays and powders.

If we want a drying, detergent and protective spray, the pine-needle oil in a two-per-cent. mixture with lavolin will accomplish the purpose, and it is a most agreeable preparation. In those cases in which the mucous glands are atrophied and in need of a powerful stimulant to excite them to action, the four- or ten-per-cent. cubeb spray is very effective, especially when combined with the ten-per-cent. solution of camphor-menthol in lavolin.

There is a prevalent mistaken opinion that the cubeb spray is drying to the mucous membrane, while the opposite effect is the true one. It is a stimulant and disinfectant; it increases the flow of mucus, and if used in too strong a preparation acts as an irritant. Cubeb is useful as a tonic in chronic irritability of the pharynx and larynx, especially in the hoarseness of public speakers and singers.

Eucalyptus is antiseptic and destructive to low forms of life. It is a stimulating expectorant, and must not be used in very strong solutions or it becomes irritant. When combined with lavolin in the proportion of twenty grains to the ounce it is not too strong for the majority of patients, but it must be

avoided in some hay-fever patients, for they cannot remain in the room when it is being sprayed without suffering from paroxysms of sneezing. Carbolic acid combined with lavolin, twenty-two grains to the ounce, is valuable when the antiseptic and anesthetic effects are required. It is very useful in ozena, especially when followed with aristol insufflations.

Camphor and menthol contracts the capillary blood-vessels of the mucous membrane, reduces swelling, relieves pain and fulness of the head or stenosis, arrests sneezing, checks excessive discharges, and corrects perverted secretions. It possesses antiseptic qualities also. Since the introduction of this remedy by the author at the meeting of the Mississippi Valley Medical Association in 1891 it has come into quite general use for catarrhal conditions of the respiratory passages.

Although the writer did not recommend it until long after he had discovered that the union of these two camphors resulted in a fluid of the chemical formula  $C_{10}H_{18}O$ , and after becoming satisfied that we possessed a valuable remedy in this new drug, he is now able to express greater confidence and to verify former statements by the experience of others as well as by the daily use of it up to the present time.

The field of application in which camphor and menthol has proved most efficacious is in the following diseases: Coryza or acute cold in the head, hay fever, alternating nasal stenosis, hypertrophic rhinitis, simple sore throat, and acute inflammation of the larynx, trachea, and bronchial tubes. In office treatment he employs the ten-per-cent. solution in lavolin, throwing a copious vapor into the nose, throat or bronchi by means of the dilator or the universal vaporizer. For use with the Davidson or the lavolin atomizer the three-per-cent. solution is sufficiently strong, and for very sensitive patients, like hay-fever sufferers, it is better to begin with a solution not stronger than one or two per cent. Very gratifying results are obtained by prescribing these weak preparations for home treatment, especially on retiring at night. The lavolin is a bland and soothing protective to the membrane, and in the combinations indicated we have a most effective and harmless remedy. This means a great deal to both patient and physician, for many of the sprays in use afford indifferent results—or worse.

In diphtheria, croup, etc., in infants, when

it is very difficult to throw a spray into the throat, the medicine may be made to reach the parts by volatilizing it, by placing a few drops of the pure, undiluted camphor-menthol in a teakettle of hot water and causing the patient to breathe the medicated steam, or a few drops can be heated in a spoon over a lamp, and its fumes will impregnate all the atmosphere of the room. Enough medicine need not be used to cause uncomfortable smarting of the eyes. Inflammation of the throat, larynx, trachea and bronchi can be effectually treated by inhaling the camphor-menthol steam in this manner.

Much suffering can be prevented in people who take cold easily by using the pocket camphor-menthol inhaler. By taking a few inhalations from this simple instrument as soon as an attack of cold in the head is felt to be approaching, the symptoms are relieved. Patients who carry the inhalers in their pockets for timely use are able to prevent sieges of colds during the seasons when they have heretofore suffered repeatedly.

#### DIABETES MELLITUS.

Dr. ORD in the London *Practitioner* for February, 1897, in giving a course of lectures on renal diseases, also speaks of diabetes and directs as to its treatment. As he states the treatment of diabetes of the typical kind is generally laid down as follows: That you cut the patient off from every kind of aliment which may be broken down to form sugar; you take away, of course, sugar itself—cane sugar; you take away all starches as starches, and you take away sweet vegetables, potatoes, everything that contains the carbohydrates; and you put the patient on a diet which is mainly one of proteids and fat, including plenty of meat and green vegetables which contain no starch. You replace bread by gluten in some form, or by almonds variously prepared. These contain cellulose, and not starch, and do not yield sugar. In bad cases you are supposed not to give him milk, because of the sugar of milk. The diet thus instituted when carried out with completeness certainly becomes after a time excessively wearisome to the patient, for the craving after carbohydrates, always considerable, grows with the prolonged deprivation. It is an exaggeration of the diet which the late Mr. Banting used for taking down that fat which he called his parasite. Well, if you do your duty according to the usually received instructions, you will take care to carry this

out. When you have done it is not certain that you have done altogether the wisest thing, for, supposing you put a diabetic patient upon such a diet, you do not stop sugar in the urine; it still comes, although in diminished quantity, and it comes either from the breaking down of animal foods into sugar, or from the breaking down of the constituents of the body itself. And it appears to be also a very serious thing that we should be introducing into the system in such large proportion the nitrogenous foods which may become themselves sources of irritation of the liver itself and very often of the kidneys. It has long been for the writer a matter for very grave consideration whether we are not in the habit of carrying this restricted diet too far. You will remember that, after all, the presence of the sugar is in one sense a very undesirable thing; in another sense a symptom of something which you cannot reach, a symptom possibly of some condition of the central organs which may be actually in itself injuriously affected by such diet. It must be admitted that the sugar is not altogether a symptom; it is, no doubt, an irritant, but still one cannot help keeping the other possibility in mind.

A few words may be said next regarding the treatment of diabetes by drugs. So far as is known the more marked cases are not curable in spite of many assertions of cure. But something can be done to reduce the excretion of sugar and to help the sufferer. We owe to Dr. Pavy the important help afforded by codeia. Experience has taught us that opium has a power of diminishing glycosuria and of controlling many of the accompanying distresses. Opium, however, has the drawback of exerting a constipating influence, while regular action of the bowels is desirable. Codeia possesses the moderating power, and is less prone to produce constipation. It may be given with advantage in doses of one-half of a grain twice or three times a day. Arsenic, perchloride of iron, the mineral acids and mercury have their supporters, but are mainly applicable to the relief of particular accessory symptoms—*e.g.*, of skin and nerve troubles, of anemia, and of disorders of digestion.

#### MALIGNANT DISEASE OF THE STOMACH.

In the London *Practitioner* for February, 1897, DOUGLAS POWELL, after discussing the subject of malignant disease of the stomach, concludes his article by giving particular attention to treatment. He says: "You can

do very little in the way of treatment, except of the palliative kind, in these cases. In the case of scirrhus pylorus, where there is obstruction and dilatation of the organ, you can do very much to keep your patient going by washing out the stomach, and then giving a meal of peptonized beef-tea, which it would rapidly absorb. In encephaloid disease you must be very wary how you inject fluids, because you have to deal with a soft, disintegrating mass, and you are apt to bring about perforation or hemorrhage by distending the stomach with fluids. When the patient ceases to be able to take food by the stomach without very severe pain, you can still keep him free to a certain extent from the pangs of starvation by rectal feeding; and you can keep him more or less from suffering by a sufficient amount of morphia. Cancer is one of those diseases in which you are completely justified in keeping your patients under the influence of sedatives such as may be necessary to secure their freedom from suffering. A small subcutaneous injection in the forenoon and a larger one in the evening will often keep a patient comparatively happy. In cases of ulcerative cancer you will do even better by giving by the stomach small doses of morphia at frequent intervals—such quantities as one-eighth of a grain of morphia."

---

*REMARKS ON THE TREATMENT OF BUBONIC PLAGUE.*

It is to be hoped that only the foreign and colonial readers of the *GAZETTE* will have reason to read this article for the purpose of putting its suggestions in practice, and fortunately but few of those will, we trust, be so tried in their professional work; but the statements of CANTLIE in regard to the therapy of this historic disease cannot be ignored by any of us who are interested in medicine. He tells us that when the patient is first seen the foul state of the tongue, the foul breath, the jaundiced tinge of the conjunctivæ, and a generally bilious aspect, suggest a purge. For this purpose calomel in five-grain to ten-grain doses recommends itself. This is to be followed by a saline in some five hours' time. Against this treatment it may be argued that the drain upon the system and the lowering action of calomel are deleterious, but if given quite early in the disease and not when the pulse is flagging, it undoubtedly seems to do good. It frequently stops vomiting, which is often present; it clears away the jaundiced aspect, it restores the power of taking nour-

ishment, and it seems to diminish mental aberration and cardiac distress. If a full gall-bladder justifies the exhibition of calomel, post-mortem evidence of that condition is not wanting. So far as is known, bacilli of plague escape from the body in greatest numbers by the bowel. In the breath, sweat or urine bacilli are but sparsely met with, but in the feces a rich supply is found. This points to the necessity of ample disinfection as being requisite for all latrines, bedpans, closets, etc., but it also proclaims as justifiable and rational the attempt to assist Nature in expelling the poison of plague by a free action of the bowels.

From the very first onset, or certainly after twenty-four or forty-eight hours, it will be found necessary to stimulate the plague patient by food, by alcohol, or by medicine.

Unless actually delirious there is not usually much difficulty in feeding plague patients. In fact, in comparison with allied ailments, the appetite is wonderfully good. One encourages this in a general way, but the occurrence of sudden death supervening after the ingestion of a bowl of rice, for example, and its accompaniments, in the case of Chinese patients on several occasions, leads one to the belief that a full meal is not without its danger. The heart is in such a condition that it takes but little to disconcert its rhythm, and the pressure consequent upon a full stomach is calculated to do this. Food should be in small quantities frequently repeated and of a kind which is easily digested. Extract of beef, in fluid or jelly form, is excellent. Ox-tail soup, mutton broth, beef- and chicken-tea should be constantly on hand to suit the varying palate of the patient. Conjee water—that is, the water in which rice is boiled—is useful as a drink and serves as nourishment. Milk with ice (sipped slowly) and ice cream (Lowson) are particularly grateful.

Thirst is at times a marked symptom, and its relief should be attended to by allowing the patient anything in reason. Ice to suck, if not kept up too long; water or lemon and water (not lemonade) to drink, if not in such quantity as to distend the stomach; beer and stout (iced), especially for Europeans, is "at once stimulant, soporific, nutritious, and thirst-quenching" (Lowson). Brandy or whiskey diluted with not more than three or four times its volume of water (not aerated waters) should be freely supplied. When the pulse shows signs of failing, or collapse or faintness supervene, then of course alcohol is doubly

beneficial, and brandy is preferable to whiskey as a cardiac stimulant.

When active the delirium of plague is best combated by cold to the head. Leiter's coil would be perhaps the readiest method, provided the patient could be kept still, but an ice-bag or a constantly wetted cloth is efficient. These applications combined with tepid sponging of the body at frequent intervals seem grateful to the patient, are useful means of reducing temperature, and seem the safest and readiest method of quieting active delirium.

In most cases, but not in all, hyoscine administered hypodermically in doses of  $\frac{1}{100}$  of a grain is perhaps the most efficient and safest of the hypnotics. It calms the nervous system and induces sleep when everything else fails. Hyoscine should be one of the first drugs in the armamentarium of a plague hospital.

At times nothing but morphine administered hypodermically in doses of one-eighth to one-fourth grain is of avail. *A priori* one would not select it as a hypnotic or anodyne, but experience has proved it to be reliable, and not so unsafe as to exclude its use. It is almost certain that when painful adenitis complicates the cerebral intoxication, morphine effects its purpose. The safest method of administration is in combination with atropine.

An occasional dose of bromide of potassium during delirium is useful and without danger, but prolonged use is not permissible.

An occasional looseness of the bowels should not be stopped unless it continues over twelve hours and the patient seems exhausted thereby. It is but seldom obstinate, and yields to salol in ten-grain doses, or to an enema of starch and opium; or, still better, a suppository of morphine and cocaine, one-fourth grain and one-half grain respectively, more especially when continued straining persists (Lowson).

Vomiting frequently ushers in an attack of plague, and may persist throughout the illness. When the latter condition obtains it is an unfavorable sign, as loss of strength ensues owing to the rejection of food and medicines. A mustard plaster to the epigastrium, ice to suck, and an effervescent draught of a few drops of hydrocyanic acid and liquor morphinæ are generally sufficient to check this untoward symptom (Lowson).

Pyrexia no doubt accounts for some of the delirium, the restlessness, the headache, and subsequent collapse. Hyperpyrexia is excep-

tional. The usual chemical antipyretics, antipyrine and phenacetine, are such severe depressants that they are at a discount and should not be used. Should hyperpyrexia necessitate its use, one hypodermic of antipyrine is no doubt justifiable as a last resource. Frequent sponging with tepid water, ice to the head and nape of the neck, iced drinks, and a short application of the wet pack, with the administration of brandy by the mouth or by the rectum, are useful when promptly and rationally used.

Flying blisters of mustard to the limbs, abdomen, and over the heart are useful. Smelling-salts and strong ammonia applied to the nostrils often succeed in restoring the pulse, rousing the patient in collapse, and not infrequently cause him to rally from what seems a moribund state (Lowson). Nor is this kind of stimulation of mere passing effect, for in several instances when death seemed inevitable and at hand patients have revived and actually recovered permanently.

Stimulation by hypodermic injection of ether is a treatment that gives grateful response, and must be used freely and frequently. The collapse from plague does not take place at that period of the disease when organic structures are played out, but it occurs early in the disease, in two or three days, and is therefore more of a functional or toxic than of an organic nature; consequently the use of stimulants in any form is more likely to be attended by remedial results and not by a mere temporary flicker of response.

Internally the form of drug most useful is either a general stimulant such as ammonia, or a cardiac tonic or specific.

The prescription of every practitioner who treats plague will be found to be one in which carbonate of ammonia and the tincture or decoction of cinchona are met with, and with this mixture, now given, now withheld, will be exhibited digitalis, strophanthus, or camphor. More good is ascribable to ammonia in some form than to any other known and more specific drug.

Digitalis in infusion, tincture, or in leaf, the latter perhaps the best, seems the one drug called for when the pulse becomes dicrotic and the nervous stimulation of the heart gives out. In practice, however, it is unsatisfactory, and seldom can any good results be traced to its administration. No doubt the slowness of its action is against it; but, what is still more, positive evidence is against its being considered a reliable drug in an acute illness like plague.

*Strophanthus* is in the same category with *digitalis*.

Camphor in its double action, as a direct cardiac stimulant and a stomachic carminative, is useful as an alternative drug. Undoubtedly the best form is in pill in doses of two grains. Camphor may advantageously be used hypodermically dissolved in sterilized oil. Caffeine also is worthy of a trial.

Musk, in the few cases treated therewith, seems to justify its administration, and it is a form of circulatory stimulant which one welcomes as an addition to one's resources. The musk, as fresh as can be obtained, may be given in five-grain doses every six hours as an expedient.

Strychnine administered by the mouth or hypodermically is of the greatest use. Granted that a functional abeyance of the nervous influence, more especially of the heart, is the essence of the toxic effect of the plague bacillus, strychnine ought to be a drug of importance in the treatment. This expectation was borne out in practice, and Dr. Lowson in his report, and all who have reported on the treatment of plague, regard strychnine as a most reliable agent in the form of stimulation required in plague. Liquor strychninæ in five- to ten-minim doses given every four hours is the most convenient form; but when vomiting is present a hypodermic solution of  $\frac{1}{8}$  of a grain of the sulphate of strychnine in ten minims of distilled water is advisable.

Other drugs may be mentioned, but though useful as a change and a standby on occasions, they do not justify more than a passing notice. Among the more important are: quinine when malaria complicates the disease, as evidenced by a large spleen; aconite in the early stages, when high fever and a full pulse are present. Chloride of ammonium as an alterative is occasionally useful.

The inhalation of oxygen (Lowson) is not to be neglected, and the gas ought to be always at hand and ready for immediate use.

The result of experience gained by local, radical, or tentative treatment of the glands does not lead one to expect much benefit therefrom. That abscesses should be opened when they point, or when fluctuation is perceptible, is of course natural; but that local remedial steps should be undertaken for the purpose of affecting the course of the disease by acting on the gland is, from what we know of the pathology of the disease, scarcely rational. Injection of a swollen gland when it is accessible, as in the groin, with such

substances as carbolic acid, perchloride of mercury, or a solution of the perchloride of mercury and iodide of potassium, has perhaps a theoretical basis of justification, but practically little good can be ascribed to it. The latter-mentioned solution may have a higher claim, as in several cases in which it has been administered temperature falls and the patient seems easier. It may be, however, that the mere pricking of the tense capsule of the gland, even by needle punctures, may serve to relieve tension and thereby pain. This leads one to the belief that subcutaneous incision of the gland may be attended with beneficial results, and it is a method of surgical procedure not without precedent. Early free incision of the gland is not to be recommended, nor can excision be in any way justified. The disease is a polyadenitis, and of so extensive a nature that eradication of infected glands is an impossibility. A gland when swollen, red, and painful may be smeared with glycerin and belladonna, or poulticed to relieve pain; and when fluctuation is perceptible it should be opened, but further procedure is useless. When pus is evacuated, dusting the wound with iodoform and ensuring thorough drainage are the means by which the best results are obtainable.

Retention of urine, a frequent concomitant during the delirium of plague, renders the use of the catheter imperative.—*British Medical Journal*, Feb. 14, 1897.

#### ABDOMINAL HYSTERECTOMY COMPLICATED WITH DOUBLE OVARIOTOMY: RECOVERY.

PFEIFFER (*Boston Medical and Surgical Journal*, Feb. 11, 1897) details an interesting case of abdominal hysterectomy as follows:

The patient, an unmarried woman between thirty and forty years of age, came to the writer for examination in May, 1896. She had been examined by him in the spring of 1893, at which time she was (examination without ether) supposed to have three small fibroid tumors of the uterus. Examination now revealed one large tumor, the size of a football, solid to the touch, and a second smaller one, the size of the fist, in front of and below the first. Both seemed closely adherent to each other, firm on manipulation, and moved with the uterus as one mass. He supposed two of the fibroids found three years before had gone on enlarging, and had obscured the third.

The patient was operated upon in June,

1896. She was in the Trendelenburg position. An incision was made from above the umbilicus to the pubes, and the large tumor on coming into view proved to be an ovarian cyst. In passing the hand around the cyst to see if adhesions existed, it was ruptured at its pedicle, and a brownish fluid with black flakes escaped into the abdominal cavity. This was rapidly flushed out with sterilized water; and an incision in the collapsing cyst wall drained off the remaining fluid over the edge of the abdominal incision, the cyst wall being drawn up to overhang the abdominal wall. The cyst was freed of adhesions by dissecting off with the thumb-nail about nine inches of small intestine, after which the pedicle could be secured in the usual manner and the cyst wall cut off.
